and lead but is a mixture imitating the tint which may or may not be made of permanent materials.

On the whole, therefore, the conclusion, as far as the pigments are concerned, to be drawn from this canvas is that the accepted list of permanent pigments as used to-day is reliable with possibly two exceptions, cobalt yellow in oil, and pale cadmium yellow, while it is certainly open to question if, on the whole, chrome yellow, when properly protected, should not be included in the artist's palette.

To return to the question of the darkening of the oil, I think the evidence is conclusive, that the excessive darkening which has taken place in this case is due to the presence of lead driers. It is, I believe, at the present day, the custom of the best artists' colourmen to grind in raw oil which, if properly refined by the mediæval methods, dries quite quickly enough for practical purposes without artificial stimulation. I have long suspected that the darkening of the latter 18th century pictures and the early 19th century pictures has been due to the use of lead driers in the oils and varnishes, and these experiments certainly confirm the view that no lead driers should be used on any account for artists' purposes. In many cases copal varnish has been mixed in as a medium, such specimens being marked with a capital C. There is no indication that the colours have been better preserved by this treatment.

The most serious defect is in the canvas, the ground in many cases having flaked off.

I hope to return to this question of the canvas, and also to give the results of the examination of the other canvases in a subsequent paper.

It is however satisfactory to learn that the present selected lists of artists' pigments are reliable with the possible exception of pale cadmium, and cobalt yellow, that the present practice of protecting by an easily removed mastic varnish is justified, and that the excessive darkening of the oil on this canvas is probably due to lead driers which are excluded from the oils and varnished according to the best modern practice.

DISCUSSION.

MR. WALTER F. REID, in opening the discussion, said he had been present at a meeting of the Society at which Mr. Holman Hunt was in the chair, and on that occasion Mr.

Holman Hunt had referred to a number of experiments he was carrying out; but, personally, he never thought he would be able to hear a full account of those experiments from so competent a witness as the author. With regard to the method of carrying out the experiments, there was one thing, he thought, which was lacking from the scientific point of view: the medium with which the pigments were mixed was not known. He understood the paints were used in the plastic form in tubes; if that were so, and if some of the tubes remained, it might be possible to find out what the medium was.

PROFESSOR LAURIE, interposing, said all the tubes had gone long ago; one could only assume that either poppy or linseed oil was used.

MR. REID thought that if it was not possible to identify the medium, half the value of the experiments was gone, because it was well known that many of the pigments used were perfectly permanent in themselves, and it was only when they were mixed with a medium, put on a painting and exposed to the air, that they deteriorated. The darkening of the oil was a subject which interested him very much, because for a number of years he had carried out experiments with regard to the oxidation and darkening of linseed oil. He had brought with him that evening a specimen of linseed oil which had been oxidised as long ago as 1878; it had been treated with about one half per cent. of lead driers and then oxidised and exposed to the air. It was now a thick viscous liquid, while its colour had changed from light amber to mahogany. Nothing whatever had been added to the oil except a small percentage of lead driers, such as were ordinarily used at that time. He could not accept the view that it was the lead driers which darkened the oil; he was in possession of an almost superfluous quantity of evidence to show that that was not the case. If sulphuretted hydrogen was allowed to get at the lead, lead sulphide was formed, which was grey in colour, and did not form a dark compound with the acids of linseed oil; if finely divided lead was suspended in the oil and sulphuretted hydrogen came in contact with it, a grey and not a brown substance was formed. He had oxidised pure raw linseed oil with the same result; it darkened on exposure to light. Even if the best linseed oil was used, it would darken in time. The mellowing of an old painting was thus clearly explained, and there was no need to look for any other reason to account for it than the darkening of the medium. Knowing that to be the case—and, personally, he was sure that it was so—it was no use trying to find a drier that would not darken. Moreover, the author appeared to have overlooked the point that most pigments were mixed with white lead. When there was

a large quantity of lead in the pigment, it was unnecessary to worry about half per cent. lead driers in the oil, and in any case, the lead was not the cause of the darkening. An important point in connection with the super-oxidised oil—if he might so describe it—was that it was soluble in water and alcohol. Alcohol was one of the things used for cleaning paintings. Its action on the various soaps which were formed with the pigments used was a very complex one, about which it was impossible to generalise; but some of them were soluble in water and alcohol, which the original oxidised oil was not. That had an important bearing on the question of picture restoring, and he would like to support very strongly the view put forward by the author, that no solvents should be used on a picture. He was inclined to say that even water should not be used, although he did not know what could be employed as a substitute. If one examined the water afterwards—as he had done—one would find that soluble acid had come out of the oil into the water, and, therefore, water should not be used for washing. It was difficult to see what one could do to clean a picture; the best way, no doubt, was not to let it get dirty. If one possessed a picture painted by a good artist, it should be covered with glass, especially in our London atmosphere. A few days ago, he had taken part in a deputation to Sir Alfred Mond, who had promised to introduce legislation to prevent, as far as was possible under existing circumstances, the pollution of the atmosphere by smoke. If that could be done, and the atmosphere of London made as good as it was during the coal strike, the covering of pictures by glass might not be necessary; but at the present time, it was absolutely imperative. He had been interested to hear from the author that examination under a microscope revealed the way in which particles of soot became embedded in the paint, forming a pigment which was really more permanent than the others underneath. The choice of canvas was also an important point. Many of the prepared canvasses which were being used at the present time were shameful; most of them ought never to be used by self-respecting artists. It would be far better to do as did the old artists, and buy raw canvas, preparing it oneself with the best materials; the practice of buying canvas prepared with the cheapest rubbish that could be plastered down smoothly, was fatal to the life of any picture. He thought the true artist would always try to make his pictures last as long as possible. He strongly supported everything the author had said about restoring pictures; in most cases it was not restoration but destruction to which the paintings were subjected. He had never yet met a single restorer of pictures who could give a connected account of the process he submitted the pictures to. The nation possessed millions of pounds

worth of art treasures which could never be replaced, and which, if put in the hands of inefficient restorers, would be spoiled. No picture ought to be restored without some highly competent chemist, such as the author, being consulted.

MR. JOHN BATTEN said that in 1907 Mr. Holman Hunt was kind enough to invite the Society of Painters in Tempera, of which he (Mr. Batten) was at that time Secretary, to visit him at his studio to have a talk with him about methods of painting. He had made a few notes of that interview, which he thought might prove interesting. Mr. Holman Hunt at that time was nearly blind, and to a man whose eyes had been his very life, that must have been a great tragedy; but he showed no sign of self pity, and seemed as cheerful as a boy. The notes were as follows:—“Holman Hunt was painting ‘The Hireling Shepherd’ at the same time that Millais was painting ‘Ophelia’ They both made use of the same method in painting the brilliant portions of the pictures. Flake white, that had had all excess of oil sucked out of it by being laid on paper overnight, was laid on, and the colour painting was done over it.” Extract from Mr. Holman Hunt’s letter of November 11th, 1907, to the Secretary of the Society of Painters in Tempera:—“The use of iodine scarlet was in the painting of the cloak of Julia in the picture of ‘The Two Gentlemen of Verona’ now at Birmingham. The modelling of this was done with white and some blue on the outlines of the velvety receding folds and with umber and perhaps cologne earth in the deepest shadows of the nearest folds. This, when dry, I varnished with copal unmitigated except for some admixture of rectified spirit of turpentine, and when this was quite hard I painted the iodine scarlet, leaving the preparation to show through, as one would with water colours, in the strongest lights, and finally when this had become quite hard I worked over all, where necessary, with semi-transparent colours, again using copal, and so left it complete. This was in the year 1851, and now it is a good example of what ‘locking up’ fugitive pigments in varnish may do.” Later in the same letter, after some passages in disparagement of mastic varnish, especially when used over ochres and umbers, Mr. Holman Hunt writes:—“I think I omitted to state that I had found in the correspondence of Venetian painters that the varnish they used was the varnish of musical instrument makers, which, of course, had to dry like enamel, not affected by the heat of the hand, as mastic varnish certainly would be. This was one reason for concluding that they employed either amber or copal for their paintings.” Millais and Holman Hunt used flake white which had had all excessive oil sucked out of it, and the colour painting was

done over it while still wet with light touches, so as not to disturb the white ground. The operation had to be finished at one painting, and could not be satisfactorily retouched. The medium used by both consisted of copal varnish, poppy oil and rectified spirit of turpentine. Holman Hunt used equal quantities of each; Millais’ medium was rather thicker. Copal varnish and poppy oil did not mix readily, but could be made to do so by heating and by the addition of spirits of turpentine shortly afterwards. Maddox Brown painted ‘Christ washing the feet of Peter’ and used the same method. Holman Hunt and the early Pre-Raphaelites certainly put their faith in copal varnish. He did not know who supplied it, but it was of wonderfully good quality. It was characteristic of nearly all paintings by the Pre-Raphaelites that they preserved their purity and did not fade. One reason for that was the fact that all the excessive oil was sucked out of the flake white, as he had already mentioned, so that there was no excessive oil to darken, and the other reason was the excellence of the copal varnish used. As far as permanence of colour was concerned, the Pre-Raphaelites succeeded absolutely, but if one closely inspected their paintings, his own feeling was that their surface quality was unpleasant. They had nothing of the achievement of the Italian or Flemish painters in that respect. A curious thing about the Pre-Raphaelites was that, although they set out to paint in an ancient and foreign manner, they actually achieved the most characteristic modern English painting in existence.

MR. NOEL HEATON said he would like to emphasise what the previous speaker had said as to the importance of the medium. The durability of an oil painting depended far more on the durability of the medium than it did on the durability of the pigments. He had always understood that Holman Hunt did not paint in straight linseed oil, merely taking his pigments, ground into a paste with linseed oil, and using them straight away—as did the average painter of to-day—but aimed at using the minimum possible quantity of oil. He understood, moreover, that he employed a thickened linseed oil to a certain extent. Personally, he believed the idea that the oil painters of the Van Eyck school painted in straight linseed oil, was a mistaken one. The more he studied their pictures the more he came to the conclusion that they must have used some such medium as Holman Hunt evolved, a medium which was very much thicker, and to a certain extent less tractable, than the medium of to-day. It could be well understood why, if he was right in his surmise, the methods adopted by that school of painters fell into disuse; the average painter would not go to the trouble of using a comparatively intractable medium, any more than the ordinary artist of

to-day would take the enormous amount of trouble the Pre-Raphaelites did in experimenting to ensure the durability of their paintings. The present-day practice was to leave the selection of materials to the artists' colourman, and hope for the best. He agreed with Mr. Reid as to the darkening of the oil. It was not necessary to assume the action of sulphuretted hydrogen on the lead contained in the linseed oil, in order to account for the darkening which took place. At the same time, he quite agreed with the author that it was a disadvantage to have lead dissolved in the oil. He had spent many years in making artists' colours, and, as far as his experience went, during the time he was connected with the industry he did not know of any manufacturer who used anything but pure refined linseed oil, or in many cases refined poppy oil, for grinding the pigments. It was quite unnecessary to use lead driers, because the artist did not require his paint to dry in the same way that the house painter did. The longer the picture remained open the better it was for him, because it gave him greater opportunity of working on it. In ordinary painting, of course, driers were added because it was necessary to get the work finished quickly, and he could only assume that in the early days some artists' colourmen may have used them because they did not know enough to differentiate between the two classes of work. From the list the author had read out, it appeared that Holman Hunt's palette was practically complete, and included all the pigments available at that time. He thought most chemists would agree with the author's comments on the pigments mentioned. With regard to cobalt yellow, which the author said required further investigation, the late Sir Arthur Church, in the first edition of his book, regarded it as a perfectly permanent pigment, but he believed he materially altered his view on that in the light of further experience. It was a substance which, in theory, one would expect to be less permanent in oil than in water, owing to the fact that oxidation might take place. He could not see any reason why raw sienna should darken; it seemed to him that the only reason why it lost its colour was that it was a fairly transparent pigment, and the same action took place with it as the author described as occurring with cobalt blue. The cleaning and restoring of pictures was a very burning question at the present time, and ought to be ventilated. He thought it was absolutely necessary for the public generally, to whom the national collections really belonged, to see that no tricks were played with them. Like Mr. Reid, he had been trying to find out what the restorers actually did in "beautifying" (as the old churchwardens called it) the paintings they dealt with. He could not help thinking that in some cases they simply put fresh paint over the top of the original, so that in time the

work of the original artist would be entirely lost beneath the efforts of the cleaners.

THE CHAIRMAN (Sir Aston Webb) said that both the paper and the discussion had been very interesting. The meeting had been honoured by the presence of Mrs. Holman Hunt, who would feel, he hoped, pride and satisfaction in hearing the remarks which had been made as to the way in which her husband's pictures had lasted. Holman Hunt's picture of Claudia and Isabella had recently been secured for the national collection at the Tate Gallery, and all those who had seen it marvelled at its wonderful condition. At the exhibition which had just closed at the Royal Academy, there were also many pictures painted, some of them, fifty years ago, which were still in very good condition, although some half dozen had cracked badly. Sir Joshua Reynolds actually destroyed two very valuable Old Masters he possessed in an endeavour to discover the secret of their lasting quality, but he did not altogether succeed, because several of his own pictures had gone rather badly. The meeting appeared to be entirely of opinion that the present system of restoring pictures was unsatisfactory. That being so, and the experts, apparently, agreeing on the point, he thought it was time action was taken to enquire into the whole matter. It was well known that pictures in the national collections were restored from time to time, and he thought the public had the right to know in what way that restoration was carried out. When painters met together, their two chief topics of conversation appeared to be the colours they used and the restoration of pictures. They seemed to hold many different opinions on the latter subject. He had been told, however, of one matter in that connection which he thought was of the greatest importance, namely, that many artists of the eighteenth and early nineteenth centuries used glazes with their varnish, and a good deal of the last touching of their pictures was done with glaze mixed with varnish. If that was so, when the varnish was removed the glaze would come off with it, and in that way one would lose a great many of the original touches of the Master himself. He had also been told that Crome and Claude, and artists who painted in that manner, got a great deal of their effect by varnish; the warm colour of their sunsets was, to some extent, obtained by that means. If the varnish was removed, therefore, as had been done in some cases, no matter how much care was taken not to remove any of the paint, a certain amount of the artist's effect would be spoiled. He did not know by whom such an enquiry as he had suggested would best be conducted; possibly the Government might undertake it. Mr. Reid had mentioned the deputation which waited on Sir Alfred Mond with regard to the smoke nuisance in London.

That question had been taken up by an independent Society, who had at last prevailed on the Government to appoint a Committee which had made very useful recommendations, to which the Government had promised to give legislative effect; and, if they did so, the amount of dirt and smoke in the atmosphere should be appreciably reduced. As Mr. Reid had said, unless pictures were protected by glass they did get into a very bad state. He himself had had to deal with a picture which had hung in Newgate Street for about two hundred and fifty years. It was a large painting, about eighty feet by twelve, and depicted Charles II giving prizes to Christ's Hospital boys. Nothing appeared to have been done to it during that time, and all one could see was some white patches, which were the faces and hands of the boys. When the school removed to Horsham, the picture was washed and proved to be in very good condition; the dirt had not done as much harm to it as might have been expected. In conclusion, he would like to add his testimony to the very excellent and practical character of the author's paper. The author's services at the Royal Academy were very valuable; he taught the students how to give permanence to their work. In the case of some of it, it was perhaps hardly necessary that it should be too permanent; but if modern artists were able to make their pictures permanent, it would largely be thanks to the author. He proposed a very hearty vote of thanks to Professor Laurie for his paper.

The vote of thanks was carried unanimously.

PROFESSOR LAURIE, in reply, said he was quite prepared to admit that, given certain conditions, linseed oil which contained no driers would darken, and he was not sure what conditions were necessary to ensure its not doing so; but, if driers were present and were attacked by sulphuretted hydrogen, the colour would most certainly darken. The first thing, therefore, he thought, was to keep the lead driers out; once that was done one could see what other tricks the oil was going to play. He agreed with Mr. Batten that Holman Hunt and Millais painted on flake white. They took out the oil and added a little copal varnish, painting on the surface while it was still wet. He did not think they extracted the oil from the other pigments used, but they always mixed a little copal varnish with them. There were different views as to the desirability of that. As far as his own experience went, the rate of fading appeared to be about the same whether copal was used or not; but the use of copal produced a kind of hardness of surface to which many artists objected. Possibly his remarks as to the medium used by the early oil painters had been misunderstood. He was concerned with

the point as to whether they used egg emulsion, or oil, including in the oil a certain amount of varnish. It was probable they did mix with their oil what would be regarded to-day as very tender varnishes, but it was very difficult to say. In stating it as his opinion that they used oil, he had not meant to exclude the possibility of varnish being added.

The Secretary had suggested to him that it would be a good thing if the Society took up the question of the cleaning of pictures, and he thought it was time that was done. Those who had expert knowledge in the matter would be glad to experiment and see how far one could safely go. Whether Holman Hunt's oils darkened because of sulphuretted hydrogen or not, they did darken. The first thing to be considered was whether a darkened oil could not be bleached without using a solvent. The "Mystery Man" business in cleaning pictures had got to be stopped.

MR. A. ELPHINSTONE said that twelve years ago he carried out an experiment which consisted of laying down about half-a-dozen different mediums on very carefully prepared canvas. He used pure linseed oil, pure poppy oil, picture copal varnish, and so on. To-day he found that the pure linseed oil, laid without any pigment over perfectly dry flake white, had turned only slightly yellow, and the same applied to poppy oil. There was no lead in either of those oils. Those experiments showed that linseed oil, if used thin, but sufficiently thick not to lose its gloss, did not become much darker after 12 years. He had also laid down pure linseed oil mixed with copal varnish and pure poppy oil mixed with copal varnish, and they had turned distinctly darker, though subjected to the same conditions, than copal varnish by itself or pure linseed or poppy oil used alone. Did any known chemical action take place when copal varnish was mixed with the oils which would account for the darkening? His experience was that chrome yellow stood well, and probably better, than cadmium.

PROFESSOR LAURIE said the objection to using linseed oil as a varnish was that it would collect dirt which would get engrained in it, and that was why one wanted a varnish which could be taken off. Cobalt yellow was such a complex substance that chemists would hardly expect it to be permanent, but there seemed to be no question of its permanence in water colour, at any rate. He could not explain why a mixture of oil and copal varnish should darken more readily, but of course it was notorious that copal varnish did darken more readily than linseed oil, and that was one of the objections some artists had to using it as a medium, although others had used it successfully.

The proceedings then terminated.

CORRESPONDENCE.

CURRENCY AND DISCOUNT.

The paper by Mr. Oswald T. Falk, which was read and discussed on March 15th, gives rise to many most important considerations. One notices the great differences of opinion expressed by gentlemen all of great experience and capacity. I therefore venture to suggest a remedy for most of the difficulties of currency and discount. The remedy is that all the laws regulating currency should be abolished, leaving the people free to adopt such currency as they like, and to have as much as they want. I do not propose at present to forbid the Government to make an issue of metal and paper currency as much as the market will take, but I propose that any person or company should be allowed to issue notes of any kind they like, subject of course, to this, that no issue of notes, or metal currency, must have any such resemblance to Government notes and metal currency as to make it reasonably practicable to substitute these private notes for Government notes. Of course, nobody would take the notes of a private person or company unless he had confidence in the value of the notes, etc., but if all legal restrictions were removed, the great banks would gradually issue their own notes, and also as gradually, confidence in these notes would become general among increasing numbers. At the present moment this country (like most other countries) suffers from the monopoly of the issue of currency which is the result of a series of laws culminating in the Bank Act of 1844, the effect of which is to cause panics and also to prevent the development of industry.

I dare not ask for space for full explanation (I would refer your readers to the excellent book by Henry Meulen entitled, "Industrial Justice through Banking Reform," published by Richard J. James, 10, Ivy Lane, Paternoster Row, E.C.).

ARNOLD LUPTON.

OBITUARY.

LIEUT.-COL. SIR JAMES HAYES SADLER, K.C.M.G., C.B.—The death of this well-known administrator occurred in Brittany on April 21st, at the age of seventy. He received his first military commission in 1870 and after serving for some six years in the Indian Staff Corps joined the Foreign Department of the Government of India, gaining his earlier experience as a political officer in Mahi Kantha and Baroda. In 1892 he went to Muscat as Political Agent and in the following year was selected to be Acting Resident and Consul-General in the Persian Gulf. Subsequently, he was an Assistant Secretary to Government, and his next appoint-

ment was the important one of Political Agent for the Somali Coast. He retired from the Indian service shortly after his arrival in Somaliland, in 1897, but remained there till 1901 as Consul-General, when he became Commissioner in Uganda. From 1905 to 1909 he was Governor of the British East Africa Protectorate and from 1909 to 1914 Governor of the Windward Islands.

In 1902, while temporarily in England, he took part in a meeting of the Colonial Section (now the Dominions and Colonies Section) when, under the chairmanship of the celebrated explorer, Henry M. Stanley, a paper entitled "To the Victoria Nyanza by the Uganda Railway" was read by Commander B. Whitehouse, R.N. Sir James was elected a member of the Society in 1903.

FIBRE RESOURCES OF COLOMBIA.

Colombia's vast stretches of lands covered with fibre plants have been of little value in the past, but, according to a report by the United States Vice-Consul at Barranquilla, recent experiments have resulted in the perfection of a machine that will reduce to fibre the leaves of plants of the wild pineapple family, from which are produced some of the finest vegetable fibres known—*Bromelia Sylvestris* and *Bromelia Pinuela*. The former fibre is divisible into one ten-thousandth of an inch. It has as much tensile strength as flax. It fully as well resists the action of water, and it takes dye perfectly and with a good gloss. The Indians used it for fish nets and their mummies were wrapped in it. Some of these mummy urns recently opened showed the fibre in a good state of preservation. *Bromelia Pinuela* has also been long recognised as a valuable plant fibre, and large sums have been spent in efforts to perfect means for its mechanical reduction. Owing to its greater and more accessible supply in Colombia, this will be the one first to be produced in commercial quantities.

There are many groups of the *Bromelia* or wild pineapple family. They are known to the natives as *Pita*, *Maya*, *Chivi-Chivi*, *Pinuela* and *Penguin*, their value as to fibre and yield being in that sequence. The *Pita* leaf is about 4 inches wide and 8 to 12 feet long. The others grade down to *Penguin*, which is about 3 inches wide and 4 to 6 feet long. *Penguin* is native to Jamaica, Cuba, and other West India Islands. The others grow prolifically from 10° north to 10° south of the Equator.

These plants are impervious to weather conditions, and because of their rapid growth are not choked down by other vegetation, as frequently happens to the hard-fibre plants, such as henequen. There are vast tracts along the mountain foothills, and there are other

immense areas growing on periodically submerged lowlands. The supply and its possibilities will meet any possible future demand, even to the extent of a hundred thousand tons annually. The largest tracts in Colombia are reached by water.

Added to the fact that the supply is so bountiful is the consideration that the machine for reducing to fibre is simple and can be produced for about £100. Each machine will be capable of producing 250 pounds of fibre per day. From a ton of leaves, the gathering of which will cost about £2, there are produced 500 pounds of fibre. Labour in the interior for handling the machines can be obtained cheaply, and the production of oil in Colombia will furnish cheap fuel. The machine is producing a fibre of about 18 to 24 inches in length, with a shorter length fibre which automatically separates from the longer, of about 5 inches, for use in the manufacture of linen paper. A third part which automatically classifies itself seems to be a good food for live stock, but on account of its resilience is being bought in Barroquilla for use in upholstery.

WATER POWER IN INDIA.

Some very interesting material both for the general student and for those interested in industrial development, is contained in a publication entitled "Triennial Report with a Preliminary forecast of the Water Power Resources of India, 1919-1921," compiled by the Hydro-Electric Survey of India. In an introductory chapter the report comments upon the generally poor attempts throughout the Empire to utilise this source of energy as compared with Europe and North America, where 18 and 17.3 per cent. respectively of the available power have been developed. The figures for North America include Canadian results, so that these are not given in the returns for the British Empire, which stand at 1.7 per cent. In India the proportion falls even lower. The report says that the probable water power of India for "maximum development" is some 12,680,000 kilowatts, equal to 2½ million water horse power, of which only 1¼ per cent. is developed or in the course of development.

The report, in making a distinction between the estimates of resources, says: "No endeavour has been made to assess the discontinuous power of individual sources which may be available for six to eight months in the year. In every country this is much greater than the continuous power available on minimum flow in the worst years, but in India, where the wet season is confined to a few months, the excessive power available during the time that the effect of the monsoons is still felt, is beyond any attempt at calculation; monsoon storage

schemes are an exception, for here the whole available power is averaged throughout the year and the maximum power is also the actual. Furthermore, when the hot weather begins, there is a great rise in the discharge of all snow-fed rivers, which lengthens the discontinuous period. The Dominion Water Power Branch of Canada, which has taken up the question exhaustively, shows that the "power for maximum development" dependable for six months is very nearly double that obtainable on "ordinary minimum flow," not absolute minimum flow as in this report. "Ordinary minimum flow" is defined as being "based on the averages of the minimum flow for the lowest consecutive seven day-periods in each year over a period for which records are available." The "estimated flow for maximum development" is based upon "the continuous power indicated by the flow of the stream for six months in the year."

After describing the method followed to determine this flow, the report states that as far as it is in any way possible to indicate at present the total power shown amounts to 582,000 K.W.s or 7,400,000 electrical horse power; and as the basis is minimum to continuous power, the figures represent kilowatt years. In distribution among the chief divisions of India, Burma, North West Frontier Provinces and Punjab have the largest proportions, being almost equal. Bengal and Bombay follow at a short distance, while Assam, United Provinces and Kashmir are a long way behind, with the "rest of India" possessing only a very small share. The different projects in these areas, however, have not been examined with an equal degree of thoroughness, attention having been given most prominently to the United Provinces and Bombay. In Bihar, Bengal and a number of other provinces, only a very meagre examination has been carried out, whilst the work of plant installation has been principally in Bombay and Mysore.

A remarkable table is that which gives a summary of the probable minimum continuous water power in India. In quite a large area, including Assam, Baroda, Bihar and Orissa, Central Provinces and Berar, Central India, Cochin, and Coorg, Gwalior, Rajputana and Sikhim, the water power now developed is *nil*. In some of these areas, it is true, the probable total K.W.s is exceedingly small, as in Baroda, Central India and Rajputana, which are emphatically in the dry zone. In other divisions however, the probable amount is fairly large. In Assam, for example, it is 414,000 K.W.s, of which 109,000 are obtainable in areas investigated, but not developed. In Bihar and Orissa, the corresponding figures are 62,550 and 12,550, and in the Central Provinces they stand at 137,560 and 13,700. These results are disappointing, as showing how little use has been made of natural opportunities; and the figures

for these areas in which some development has taken place, with the sole exception of Jammu and Kashmir and Bombay, afford very little consolation. In Bengal for example, out of a probable total for minimum continuous water power, amounting to 669,850 k.w.s, only 600 k.w.s are in a developed state, 14,250 are in areas investigated, but not developed, while the largest portion of the Province remains to be investigated. Worse still are conditions in the North West Frontier, where, with a probable total of about 1,000,000 K.W.s, only 250 are developed. In the United Provinces, including the Canals, the figures are 403,370 and 4,330 respectively, but in this instance a very large proportion of the source has been investigated. Burma also shows a very backward condition, the actual development being 3,370 K.W.s out of a probable total of nearly a million. It may be remarked that the plant under construction is only for 55,640 K.W.s, of which 50,000 are in Bombay, 4,500 in Mysore, 1,000 Gwalior, and only 140 in the United Provinces. Summing up the figures for all the provinces, the report states that of a probable total, 5,582,300 K.W.s only 213,140 are now developed, and 3,017,000 are put down to areas and sites which have not yet been investigated.

POWER IN BENGAL.

Turning to conditions in Bengal, the report says that water power developed at present "consists only of the pioneer installation at Darjeeling." The Municipal Hydro-Electric Supply is obtained from three small nullahs, tributaries of the Rangpoet and Tista Rivers. The original development in 1896 utilised the hospital jhora and Kotwali jhora by means of open channels meeting above the confluence. Later a third nullah was brought in, and finally "the hospital jhora was tapped at the point higher up the stream, and an upper power house was built." More, however, can be said of the sites which have been examined in Bengal. In this connection the report says: "Hitherto the only site in Bengal of which the examination has been definite are in the Dooars tea planting district, in the Jaldaka and neighbouring streams. The possibility of development here turns almost entirely on the question of firing the tea leaf electrically"—a process which is discussed by the report in a separate paragraph. Altogether there are three sides, one being the Jaldaka river, the second a small project in the Moortee River, and the third in the Ne Chu (or Thodi) River. Among known sources, whose possibilities, however, have not been ascertained, are the rivers in the Darjeeling district and the Karnaphuli River, Chittagong. It may be mentioned also that the resources of Assam, both developed and undeveloped, as also the actual position and the possibilities in other provinces, are carefully described, while special prominence has been given to the canal

falls in the Punjab. In this province also the three great sides examined, the Anu, the Sutlej at Nangol and the Sutlej River project have come in for their share of attention, the Anu Khad scheme being of special interest to residents of Simla, where the demands for a hydro-electric station have become more urgent.

The report does not pretend that it has given an exhaustive account of existing possibilities or that it has made an accurate forecast of the water power of India, for the author says: "Even now any such attempt is of necessity largely guesswork."

SOUTH AFRICAN DIAMOND MINING INDUSTRY.

The estimated value of the diamonds produced in the Union of South Africa during 1920 constituted a record for the industry. The value of the mined, alluvial, and debris-washed diamonds totalled for the year the sum of £14,762,899. The bulk of this amount, or £12,289,602, came from the mines, £2,441,440 from alluvial mining, and £31,867 from debris washings. The previous record year was 1919, the output being valued at £11,734,495. Prior to 1918 the high-water mark was reached in 1913, when diamonds were produced to the value of £11,389,807.

The 1920 output aggregated 2,545,017.47 carats, of which 2,312,436.55 came from regular mines and 221,460.17 from alluvial mining; 11,120.75 carats were recovered from debris washings. It is to be noticed that production in the six years 1915-20, has been practically constant, and in the last three years of the period has fluctuated approximately by only 50,000 carats. The year 1910 is still the record by volume for the industry, 5,456,558 carats being produced.

While production value in 1920 constituted a record, the sales of diamonds fell below the total of 1919 by £3,411,257—from £13,739,662 to £10,328,405. This decrease is accounted for by the large drop in the volume of sales, which were only 1,765,993.82 carats as compared with 1919 sales of 2,648,931 carats. The sales total would have been even less in value except for the increase in the price realized, which was 117s. in 1920 against the 1919 figure of 101s. per carat. This high figure reflects the effect of abnormal conditions on prices, as the price realized per carat in 1917 was 51s. 1d. and in 1918 was 54s. 9d. That these high price stimulated production is evident in that there were 19 mines producing in the Union in 1920, compared with 16 in 1918 and 11 in 1917.

In a report dealing with the diamond industry, by the United States Trade Commissioner at Johannesburg, from which the foregoing figures have been taken, he points out that the fluctuating character of the industry is indicated by the fact that while the value of diamonds from

mines rose in value from 75*s.* 9*d.* in 1919 to 106*s.* 3*d.* per carat in 1920, the alluvial diamonds declined from 261*s.* 6*d.* to 220*s.* 6*d.* On the other hand, when the jump in the value of the alluvial output between 1918 and 1919 was from 134*s.* 6*d.* to 261*s.* 6*d.* the mine output was only increasing from 51*s.* 5*d.* to 75*s.* 9*d.*

In view of the special manner in which diamonds are marketed through the Diamond Syndicate, it is interesting to note the difference between the production and sales figures. In 1920 sales by volume were 779,024.65 carats under production. In 1919 sales were 60,813.95 and in 1918, 104,572.45 carats above the output. In 1917 the position was reversed and production exceeded sales by 586,206.90 carats, while in 1916 such excess was 54,383.33. Taking this five-year period, the total production of diamonds exceeded the total sales by 1,254,228.48 carats. During this same period the value of the output exceeded the realization value of £4,114,968.

The production within the Union is divided, in order of importance, among the Cape, the Transvaal, and the Orange Free State. The Cape contributed 1,364,706.25 carats, of which 1,258,129 were from the Kimberley mines. The Transvaal production was 905,297.05 carats, practically the whole of the 782,557.30 mine diamonds being the output of one mine. The share of the Orange Free State was 275,014.17, of which 269,178 carats were from the nine mines in that district.

The importance of the diamond industry to South Africa is reflected in the purchases of mine stores. The returns for 1919 show that the mines consumed stores in that year to the value of £1,058,050. The figures for the past few years are as follows: In 1918, £747,142; in 1917, £688,801; in 1916, £350,485; in 1915, £139,521; in 1914, £969,325; in 1913, £1,645,219. In 1912, £1,466,151; and in 1911, £1,450,127. It is evident from these statistics that during the past few years purchases have not come up to the pre-war figures despite the higher price levels that now prevail. Some of the principal items in 1919 were: Coal, £185,063; dynamite, etc., £120,481; candles, £22,097; belting, £9,928; safety fuse, £34,250; hand tools, £11,991; lubricants (oils), £21,756; machinery and machine tools, £33,558; rails, sleepers, etc., £37,955; sheet steel, £24,146. Of these items, all of the coal and dynamite and practically all of the candles were produced in the country itself.

ADVERTISING IN SOUTH AFRICA.

Entirely different methods of advertising should be followed in the different Provinces of South Africa, according to advice furnished by the United States Consul at Johannesburg. As an example, the Transvaal may be regarded as a huge mining district, Johannesburg being

the centre. Money circulates freely, and business is carried on in a so-called rough-and-ready manner. The characteristic of buyers is that they require a concise, detailed account of the article and a fixed price. In the Cape Province, however, the people are more conservative, probably more thrifty, but do not have the same amount of money to spend. Cape Province has been settled longer and conditions there approach those of an older civilization more than do those in the Transvaal. Cape Town is the centre of whatever art there is in South Africa and consequently artistic advertising is of greater value in the Cape Province than in the more recently settled portions of the Union. Under these conditions it is evident that a waste of money results in sending out copy for general use throughout the country.

There are other points which should be borne in mind when placing advertising in South Africa, such as differences in climate of the various Provinces, the South African's lack of knowledge of many things which are in common use in European countries and the United States, and the inferior quality of paper used in publications which will not give good impressions of fine blocks.

COTTON GROWING IN THE ARGENTINE CHACO.

Many efforts have been made by public authorities and by private enterprise to stimulate the growing of cotton in the Chaco Territory of Argentina and on other suitable lands in the Republic, but the stimulus of high prices proved more effective than other means of encouragement, and cotton acreage increased to a measurable extent during the last few years.

The first cotton gin is said to have been brought into the country in 1863 as a result of attempts made during the American Civil War to introduce cotton growing into Argentina. At various times the distribution of free seed and exemption from taxation have been resorted to without appreciable results; prizes have been offered, and in various competitions good samples have been submitted. However, writes the United States Consul at Rosario, not much headway was made until after the outbreak of the war in 1914. The stimulus of war prices on the cotton industry is reflected in the acreage planted to this crop which for the five years 1915-19 as follows: 1915, 8,414 acres; 1916, 7,001 acres; 1917, 26,847 acres; 1918, 29,947 acres; 1919, 34,200 acres.

The growth of this industry in the Chaco Territory alone is indicated by the following statistics (showing hectares cultivated), compiled by the State Railway officials: 1918-19, 5,541 hectares; 1919-20, 9,010 hectares; 1920-21, 22,920 hectares. (Hectare equals 2.47 acres.)

Private estimates ascribe 12,000 hectares to the Province of Corrientes in 1920-21, and a small amount has been grown experimentally in other Provinces.

Many varieties have been tried, including Egyptian, Sea Island, Russell, Georgia, Pettekin, Culpepper, Simpkins, Manila, and Texas Wood. The Egyptian cotton did not prove adaptable, and the best results have been obtained with Upland short staple. Most of the cotton now raised is known simply as Chaco cotton, which is understood to be an acclimatised variety of Russell cotton. It is a clean white cotton with irregular fibres from an inch to an inch and a quarter in length.

Planting is done during September and October in the Chaco and in Corrientes, and picking begins about the middle of February. Ten kilos of seed are estimated as necessary for seeding one hectare, and the yield is estimated at between 1,000 and 1,500 kilos. The yield of seed per hectare rapidly decreases as the land becomes exhausted.

As a result of the high prices obtained in 1920 a considerable extension of acreage occurred and in some districts, as for instance in the county of Goya, Corrientes, tobacco culture was abandoned in favour of cotton growing, while in many other counties in the same Province cotton acreage was increased.

Exports of raw cotton were included for the first time in 1920 in official reports of exports of the country's products. The quantity shipped during the year amounted to 4,120 metric tons; the annual exports during former years are unofficially estimated to be 3,065 bales in 1912, 1988 bales in 1913, and 1,242 bales in 1914. In comparing these figures, however, consideration should be given to the much larger importation of raw cotton and to the enormous importation of cotton yarn and textiles. Native cotton is used for the domestic manufacture of absorbent cotton, for mixing to some extent with other textile fibres, for match stems, and as waste, and is sold by sample instead of by grade. On account of its short fibre it can scarcely be considered a competitor with the imported cotton.

The difficulties of extending cotton production in Argentina consist largely in the lack of labour and the unfavourable climatic conditions of the northern valley lands. The land available is practically unlimited, but it will be necessary to clear it, combat semi-tropical conditions, establish settlements, and import labour before the industry can become well established.

An annual competition has been established by the Museo Agrícola de la Sociedad Rural in Buenos Aires for the display of samples of native cotton, and in the 1920 competition 75 growers applied for representation and 41 submitted samples which comprised Chaco, Texas, Wood, and Russell varieties.

GENERAL NOTES.

INSECT PESTS OF RAW COCOA.—Most foodstuffs, when stored, are liable to be attacked by insects, and the damage thus caused amounts in the aggregate to millions of pounds every year. Perhaps the best known pest of this kind is the grain weevil, which destroys enormous quantities of wheat and other cereals, particularly in countries such as Australia and Canada, where vast stocks of grain are stored while awaiting shipment. The depredations of such insects extend even to raw cocoa and it has been estimated that the proportion of "grubby" beans in the world's production of cocoa is on the average from one to two per cent. This subject was considered at the Rubber and Allied Industries' Exhibition, held in London this year, when Mr. A. W. Knapp, of Messrs. Cadbury Bros., Ltd., read an interesting paper on Insect Pests in the Cocoa Store, which is printed in the current number of the Bulletin of the Imperial Institute. The most frequent pests are the caterpillars of small moths, particularly those of the Mediterranean flour moth, which are often found in mills and granaries; minute beetles too are commonly present. Various methods have been tried for destroying the insect attacking the cocoa, including fumigation with chemicals and spraying with insecticides. The most effective method, however, appears to be the application of heat, since this kills the eggs as well as the larvae and adult insects, whilst, provided the temperature of 160°F is not exceeded, the cocoa is not detrimentally affected.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.—An Exhibition of Contemporary British Architecture will be held in the Galleries of the Royal Institute, 9, Conduit Street, W.1., from November 1st to December 16th, 1922. All architects in the British Empire are invited to submit their work. Exhibits may consist of photographs, elevations, perspective drawings and small scale plans. The last day for the receipt of drawings and photographs will be October 7th, 1922. The Exhibition will be open to the general public (free) between the hours of 11 a.m. and 6 p.m.

SILK CULTIVATION IN BRAZIL.—The Brazilian Ministry of Agriculture, through its sericulture experiment station at Barbacena, in the State of Minas Geraes, has made sufficient headway for the incorporation of a company to erect a modern silk factory at Campinas, Sao Paulo, writes the United States Assistant Trade Commissioner at Rio de Janeiro. Mulberry trees are grown with considerable success in Brazil, and silk worms have so far escaped serious epidemics. The quality of Brazilian silk is claimed to be of the best, withstanding all unfavourable effects of washing.

MEETINGS OF THE SOCIETY.

ORDINARY MEETINGS.

Wednesday evenings, at 8 p.m. (unless otherwise announced):—

MAY 10.—MAJOR PERCY A. MACMAHON, R.A., LL.D., ScD., F.R.S., "The Design of Repeating Patterns for Decorative Work." SIR MARTIN CONWAY, F.S.A., M.P., in the chair.

MAY 24.—GEORGE FLETCHER, Department of Agriculture and Technical Instruction for Ireland, "The Natural Power Resources of Ireland." SIR GEORGE T. BEILBY, D.Sc., LL.D., F.R.S., Director of Fuel Research, in the chair.

MAY 31 (at 3 p.m.)—LAWRENCE HAWARD, M.A., Curator of the City Art Gallery, Manchester, "The Manchester Art Gallery and the Problem of Provincial Collections."

INDIAN SECTION.

Friday afternoons at 4.30 o'clock:—

MAY 26.—SIR THOMAS W. ARNOLD, C.I.E., D.Litt., M.A., Professor of Arabic, School of Oriental Studies. (Sir George Birdwood Memorial Lecture.) "Indian Painting and Muhammadan Culture."

JUNE 23.—F. W. WOODS, C.I.E., late Chief Engineer, Irrigation Department, Punjab, "Irrigation Enterprise in India."

Date to be hereafter announced:—

J. T. MARTEN, I.C.S., M.A., "The Indian Census."

DOMINIONS AND COLONIES SECTION.

FRIDAY, JUNE 9, at 4.30 p.m.—MAJOR SIR HUMPHREY LEGGETT, D.S.O., R.E., "Tanganyika Territory (formerly German East Africa)."

MEETINGS OF OTHER SOCIETIES FOR THE ENSUING WEEK.*

MONDAY, MAY 8.—Geographical Society, 135, New Bond Street, W., 8.30 p.m., Mr. R. Bryce, "The Klagenfurt Plebiscite." University of London, King's College, Strand, W.C., 5 p.m., Prof. G. B. Gray, "The Place of Sacred Gifts in Hebrew Practice and Thought." (Lecture I.) At Bedford College for Women, York Gate, Regent's Park, N.W., 5.15 p.m., Prof. F. Baldensperger, "Une Destinée Littéraire Anglo-Française: Alfred de Vigny." (Lecture II.) Surveyors' Institution, 12, Great George Street, S.W., 8 p.m. Brewing Institute of, at the Institute of Chemistry, 30, Russell Square, W.C., 8 p.m., Mr. A. H. Paul, "The Delivery of Beer in Bulk." Royal Institution, Albemarle Street, W., 5 p.m. General Meeting. Chemical Industry Club, 2, Whitehall Court, S.W., 8 p.m., Dr. E. F. Armstrong, "Chemical Progress: Some Impressions of 25 Years." TUESDAY, MAY 9.—Petroleum Technologists, Institute of, at the ROYAL SOCIETY OF ARTS, John Street,

Adelphi, W.C., 5.30 p.m., Mr. E. H. Cunningham-Craig, "Kukkersite, the Estonian Oil-Shale."

Photographic Society, at the ROYAL SOCIETY OF ARTS, John Street, Adelphi, W.C., 8 p.m., Prof. Svedberg, "The Interpretation of Light Sensitivity in Photography." (Hunter and Driffield Memorial Lecture.)

Anthropological Society, 50, Great Russell Street, W.C., 8.15 p.m., Captain M. W. H. Simpson, "Some Ethnographical Researches among the Berbers of Algeria."

Colonial Institute, Hotel Victoria, Northumberland Avenue, W.C., 8.30 p.m., Lord Lee of Fareham, "The Washington Conference."

Anglo-French Society, Scala House, Tottenham Court Road, W., 6.15 p.m., M. M. Thiéry, "Le Drame en Vers, Henri de Bernier et François Coppée."

Royal Institution, Albemarle Street, W., 3 p.m., Prof. Sir Arthur Keith, "Racial Problems in Africa." (Lecture III.)

WEDNESDAY, MAY 10.—People's League of Health, at the ROYAL SOCIETY OF ARTS, John Street, Adelphi, W.C., 6 p.m., Prof. C. S. Myers, "Industrial Life, its Hours of Work, Fatigue and Rest Pauses."

Geological Society, Burlington House, Piccadilly, W., 5.30 p.m., 1. Prof. E. J. Garwood and Miss E. Goodyear, "The Lower Carboniferous Succession in the Settle District and along the Line of the Craven Faults." 2. Mr. E. J. Wayland and Dr. A. Morley Davies, "The Miocene of Ceylon."

Literature, Royal Society of, 2, Bloomsbury Square, W.C., 5.15 p.m., Professional Lecture. Automobile Engineers, Institution of, at the Institution of Mechanical Engineers, Storey's Gate, S.W., 8 p.m., Mr. J. Watt, "Automobile Calculations: Practical Methods for the Designer."

THURSDAY, MAY 11.—Chadwick Public Lecture, at the ROYAL SOCIETY OF ARTS, John Street, Adelphi, W.C., 5.15 p.m., Sir Lawrence Weaver, "Rural Re-settlement and its Relation to Public Health." (Lecture II.)

Royal Institution, Albemarle Street, W., 3 p.m., Prof. F. Keeble, "Plant Sensitiveness." (Lecture I.)

Central Asian Society, at the Royal United Service Institution, Whitehall, S.W., 5 p.m., Brig.-Gen. Sir Percy M. Sykes, "Persia, 1916-1919."

Historical Society, 22, Russell Square, W.C., 5 p.m., Miss G. S. Thomson, "The Office of Deputy-Lieutenant and its Historical Significance."

Optical Society, at the Imperial College of Science and Technology, South Kensington, S.W., 7.30 p.m.

University of London, at King's College for Women, Campden Hill Road, W., 4.30 p.m., Prof. V. B. Mottram, "Metabolism of Fat and Allied Substances." (Lecture II.) At the Birkbeck College, Bream's Buildings, Fetter Lane, E.C., 5.30 p.m., Prof. Dr. J. C. Shoute, "Whorled Phylotaxis."

Electrical Engineers, Institution of, Savoy Place, Victoria Embankment, W.C., 6 p.m., Sir E. Ruthford, "Electricity and Matter." (Kelvin Lecture.)

Royal Society, Burlington House, Piccadilly, W., 4.30 p.m.

Antiquaries, Society of, Burlington House, Piccadilly, W., 8.30 p.m.

FRIDAY, MAY 12.—Astronomical Society, Burlington House, Piccadilly, W., 5 p.m.

Malacological Society, at the Linnean Society, Burlington House, Piccadilly, W.

Royal Institution, Albemarle Street, W., 9 p.m., Dr. H. H. Dale, "The Search for Specific Remedies."

Anglo-French Society, Scala House, Tottenham Court Road, W., 6.15 p.m., Mr. S. Jamal, "The Conflict in Palestine."

University of London, at the London School of Economics, Houghton Street, W.C., 5 p.m., Dr. P. Giles, "Modern Views of Indo-European Origins." (Lecture I.) At the Birkbeck College, Bream's Buildings, Fetter Lane, E.C., 6 p.m., Dr. E. J. Russell, "Recent Work with regard to the Influence of Soil Conditions on Agriculture." (Lecture I.)

Physical Society, at the Imperial College of Science and Technology, South Kensington, S.W., 5 p.m.

SATURDAY, MAY 13.—Royal Institution, Albemarle Street, W., 3 p.m., Prof. O. W. Richardson, "X-Ray and Ultra Violet Spectra." (Lecture I.)

Journal of the Royal Society of Arts.

No. 3,625.

VOL. LXX.

FRIDAY, MAY 12, 1922.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C. (2)

NOTICES.

POSTPONEMENT OF ORDINARY MEETING.

In consequence of the engineering lock-out, Mr. Oswald M. Shepherd, who was to have read a paper on May 17th, on "Recent Developments in Rubber Manufacture, with special reference to Rubber Machinery and the Manufacture of Tyres," has been unable to complete his researches, the results of which he had hoped to bring before the Society. It has, therefore, been found necessary to postpone his paper until next session.

TWENTY-FIRST ORDINARY MEETING.

WEDNESDAY, MAY 3rd, 1922 ; MR. ALAN A. CAMPBELL SWINTON, F.R.S., Chairman of the Council, in the Chair.

The following candidates were proposed for election as Fellows of the Society :—
Howgrave, Walter, Addiscombe, Surrey.
Marshall, Henry, M.S.A., Calcutta, India.
Muirhead, Alexander, C.I.E., London.
Pearson, Nels August, Rancagua, Chile.

The following candidates were balloted for and duly elected Fellows of the Society :
Dawson, Frederick Lawrence, Pyapon, Burma.
Risdon, Philip James, London and Hove, Sussex.

A paper on "The Production of Titanium Oxide and its Uses as a Paint Material," was read by Mr. Noel Heaton, B.Sc.

The paper and discussion will be published in a subsequent number of the *Journal*.

DOMINIONS AND COLONIES AND INDIAN SECTIONS.

FRIDAY, MAY 5th, 1922 ; THE RIGHT HON. VISCOUNT BURNHAM, C.H., Chairman of the Empire Press Union, in the Chair. A paper on "Imperial Wireless Communication," was read by PROFESSOR W. H. ECCLES, D.Sc., F.R.S.

The paper and discussion will be published in a subsequent number of the *Journal*.

PETER LE NEVE FOSTER PRIZE.

The Prize of £10 and a Silver Medal, offered under the Peter Le Neve Foster Trust, for an Essay on "The Mineral Resources of China," has been awarded by the Council to Mr. C. Y. Wang, Consulting Mining Engineer, of Hankow.

PROCEEDINGS OF THE SOCIETY.

EIGHTEENTH ORDINARY MEETING. SHAW LECTURE.

WEDNESDAY, MARCH 29TH, 1922.

SIR ROBERT ARMSTRONG-JONES, C.B.E., M.D., F.R.C.P., in the Chair.

The CHAIRMAN, in introducing Sir Thomas Oliver, said that he occupied a very eminent position as the leading consulting physician in the North of England, and he had made valuable contributions to the literature of industrial hygiene, which were known beyond the confines of our own country. His investigations into the deleterious effects of lead in industry had been of the greatest value to employers and employees. They had guided and directed legislation in this and other countries, and his investigations had not only preserved the health of the workers, but had saved many lives by prevention. He was personally indebted to Sir Thomas Oliver for much of the knowledge he possessed in regard to lead poisoning, and the lecturer's contribution upon industrial diseases to Clifford Allbutt's system of medicine, would remain the most reliable classic for reference. His lecture that night was upon the relation of alcohol to industrial efficiency and they were fortunate to have as its exponent such a brilliant scientific and impartial investigator.

ALCOHOL IN RELATION TO INDUSTRIAL HYGIENE AND EFFICIENCY.

By SIR THOMAS OLIVER, M.D., F.R.C.P.

If this country is to regain her pre-war industrial prosperity, it is desirable that

every circumstance which retards her recovery should receive careful consideration. Into the causes which have led to the present unfortunate state of British trade and finance it is not the purpose of this address to enter. What the nation requires, and what is absolutely necessary for the people, are that there shall be a better understanding between capital and labour, that taxation shall be lessened, Governmental control of industries abolished, that men must work so that production be increased, also that old markets must be regained and new markets found. Given these, there must also be industrial efficiency. It is to one aspect of this question that I am invited to draw your attention, viz., to alcohol and industrial efficiency. The subject must be dealt with temperately and, as far as possible, without bias. The increasing use of machinery in production is diminishing the amount of hand labour, and while in one sense machinery lightens labour, in another it creates conditions which not only impose heavy demands upon those who supervise the running of the machinery, but induce a form of fatigue, partly a consequence of the environment in which work is carried on. The fatigue and monotony of modern factory life call for considerable rest of body and mind. Tiredness is a cause of industrial inefficiency and of accidents as well. A craving for excitement and recreation is, a sign of a jaded nervous system; so, too, in some instances is a craving for stimulants, whereby the depressing influences of work may be removed. Customs die hard, and yet, on the whole, it may be said that there is less heavy drinking among all classes to-day than there was a few decades ago. Factory work is run on a higher plane and there is not the temptation afforded to men to obtain rum and milk in the early morning on their way to work. To-day the artisan resumes his day's toil after having breakfasted at home, without, on his way to the factory, having the opportunity of purchasing stimulants. The occasions are few where a man who is under the influence of liquor and presenting himself at the factory gate gains admission, or even if he does that, if recognised, would be allowed to work. It is not with this type of case, however, we are immediately concerned. We draw a line between drunkenness and alcoholism. It is, among other things, to the after effects of alcohol as exhibited in the inco-ordinated muscular movements of workmen on the

Monday forenoon after a week-end debauch, also to the general question as to whether alcohol does or does not lead to industrial inefficiency that attention is invited. It may at once be said that alcohol should not be allowed to be consumed in a factory. When I was a member of the Dangerous Trades Committee of the Home Office, we found in certain laundries in London that at a certain hour in the forenoon persons from outside were allowed to enter the laundry and retail beer to the women. In all well-conducted laundries this custom has practically ceased.

Any enquiry into the relation of alcohol and industrial hygiene will be incomplete if it leaves out of consideration the home conditions of the worker and the manner in which he spends his leisure hours. There are also the nature of the employment, personal idiosyncrasy and hereditary influences to be thought of. It is the effect of the immoderate use of alcohol upon the producing capacity of working men by drinking habits encouraged during their leisure hours, rather than the premature development of disease and its disabling consequences, which merits consideration. There is the opinion, to which Temperance Insurance Offices lend the weight of their statistics, that in a general way, no matter what may be the occupation followed by an alcoholic subject, his life in most instances is shorter than that of a non-alcoholic workman engaged in the same trade. No one questions the harmful effects of the immoderate use of alcohol. On this point there is common agreement, and yet opinion is divided as to whether alcohol never plays a useful part in vital processes. If alcohol is a food, is it a suitable food? If it is a stimulant, conditions may arise in which its use may be called for; on the other hand, if it is such a poison, as some writers would lead us to believe, then it ought to be avoided.

The question of the use and abuse of alcohol might be considered under the following headings, viz.:—The scientific, the ethical, the social and industrial. The ethical aspect of the question hardly comes within the scope of our discussion to-night.

Dealing with the scientific aspect of the question, we ask what is alcohol? In an impure form alcohol has been known and used by men for decades of centuries. Chemists speak of it as ethyl alcohol. It is obtained from the fermentation of sugar, or from starch which has been subjected to

a preliminary ferment action. Wines and beers contain a small percentage of alcohol (2 to 20), while in spirits obtained by distillation from the simpler liquors there may be 30 to 60 per cent. of alcohol, not including certain volatile substances belonging to the alcoholic series. Opinions are divided as to the value of alcohol as a food and the part it plays in the human body in disease. There is little doubt that when concentrated it acts as a local irritant to the lining membrane of the stomach, and after it has been absorbed into the blood, that it has a special predilection for the higher nerve centres. The effects produced by its action upon the brain vary according to the quantity taken, the idiosyncrasy of the individual and the nature of the food which is present in the stomach at the time. Small quantities, taken at a public dinner, for example, may produce only a feeling of well-being and a source of increased confidence in one's powers, mental and physical; slightly larger doses may lead to excitement attended by loss of self-control, as seen in the inco-ordination of muscular movement and of speech, and accompanied by a loss of the sense of responsibility: still larger doses consumed under circumstances other than those described, may throw the individual into a deep sleep, from which with a coated tongue, he awakes nervous and depressed, and if maximum doses have been taken the sleep deepens, the individual passes into a state of unconsciousness, in which he may die through failure of the respiration. It is with alcohol, as with other drugs: all persons do not react towards it in the same way, nor the same individual at different times. We cannot ignore the personal element. As regards the effect of alcohol upon the nervous system, there are the two well-known opinions of physiologists, viz., that alcohol first stimulates and afterwards depresses the nerve cells, and the other view is that there is no primary stimulation at all, but depression from the commencement. Excitement, as evidenced in greater freedom of speech and gesticulation is not necessarily an indication of stimulation of the nerve centres concerned, for it may be the result of a weakened self-restraint over the higher centres through loss of will-power. Cushny alludes to the difficulty of coming to a decision upon this point owing to the fact that even the smallest muscular movement, simple as it may appear, is not so simple after all, but is the

result of the combination of motor and inhibitory nerve impulses proceeding from the brain. Thus the apparent self-confidence and the brilliancy of the after-dinner speech of a friend, may not be the result of increased physical strength and stimulation of brain centres, but of the influence of the surroundings in which he finds himself and a consequence of the loss of his usual shyness and nervousness.

Under the influence of alcohol upon the brain nerve force is liberated, but it is not always so well controlled and directed as under normal conditions, the stimulation is fugitive and it is replaced by depression. It is not impossible to get some good work done during the early phase of the stimulation, for even Rivers, who holds strong views upon the subject, admits that after taking alcohol an exceptional amount of work can be performed before the fatigue stage appears. While as a consequence of the imbibition of fairly large doses of alcohol, it is usually the higher and controlling centres of the brain which are first thrown out of gear, and subsequently the motor centres, as evidenced by inco-ordination of muscular movements, yet occasionally as indicating the personal element in the matter, I have known people who got drunk in their legs, who were unable to stand or walk, notwithstanding the fact that their conversational and intellectual powers, so long as they were sitting, seemed to be undisturbed.

In his experiments, Professor Edward Mellanby has gone carefully into the question of the conditions which affect the absorption of alcohol, and he found that in the main, but not always, were the effects produced upon the nervous system proportionate to the amount of alcohol circulating in the blood. Examining the blood of dogs to whom he had given alcohol by the mouth, he found that the maximum of alcohol was present in the blood one hour after the experiment, also, that while the spirit tended gradually to disappear from the blood, there were still traces of alcohol in it 19 hours afterwards. In his opinion, it requires 21 hours for the whole of the alcohol to be removed from the blood, in cases where one dose only of the drug has been administered, also, that if alcohol is administered on the second day, there is found a higher maximum of alcohol in the blood, indicating that a certain amount of accumulation has taken place. The

blood gets rid of the alcohol by a process of oxidation, and it is while this is being accomplished that a certain amount of energy is liberated within the body, which is utilizable. The larger the amount of alcohol present in the liquid consumed, so much the more quickly is the maximum of alcoholic concentration in the blood reached, also symptoms of intoxication produced—and yet there are alcoholic drinks and drinks. Whisky was found to be more rapidly absorbed than stout, even when the percentage of alcohol was the same in the two liquids, a circumstance which suggests that there is something present in stout which retards the absorption of its contained alcohol. It is common experience that alcohol taken on an empty stomach is more likely to be quickly absorbed than when food has just been previously taken. Some foods retard the absorption of alcohol more than others. Milk, probably owing to the fat it contains, particularly delays absorption, so that, to put it in Mellanby's own words, "when rum and milk are taken, the individual has the optimum state of alcoholic intoxication lasting over the maximum length of time." Mellanby was fortunate in securing the services of a man accustomed to the free use of intoxicants, who voluntarily gave himself up to be experimented upon by allowing 5 C.C. of blood to be drawn from the veins of his arms at stated intervals after the ingestion of alcohol. In this man, as in dogs, the alcohol of whisky was found to be rapidly absorbed; in him, too, the maximum alcohol content of the blood attained, as well as the intensity of the intoxication reached, were greater than where the same amount of alcohol was administered in stout. In the case of whisky, the maximum point of concentration of alcohol in the blood occurred about one hour after its ingestion, in the case of stout, not until four hours afterwards. When the alcohol content of the blood begins to decline, the symptoms of intoxication correspondingly fall. Alcohol can be fairly rapidly eliminated from the body on any particular day, but if it has been consumed freely, and the dose is repeated on the following day, the alcohol is not eliminated so rapidly, and therein lie the baneful effects of week-end drinking.

Some of the psychological effects of alcohol have been reported upon by Dodge and Benedict, who carried out experiments

in the Carnegie Institute, Washington. They studied the effect of alcohol upon the pulse rate during mental and physical work. It was Sir Lauder Brunton's opinion that alcohol in moderate doses increased the pulse rate. The opposite view was expressed by Sir Victor Horsley and Sturge. All are in a sense right, for alcohol increases or depresses the pulse rate according to the circumstances prevailing at the time. There are few subjects around which there has ranged greater controversy than around alcohol; the facts of experience and experiment do not always agree, nor are the results of experiment always identical, and the experience of medical practice uniform. Regarding the pulse rate in mental and physical work, Dodge and Benedict found that after the ingestion of alcohol there was, in almost every instance a *relative acceleration* of the pulse, meaning by *relative acceleration* a more rapid pulse than what occurs at a corresponding hour of normal days. These physiologists maintain that the increased pulse rate occurs practically in all persons as an effect of alcohol during mental and physical activities. As to the cause of this quickening we need not stop to enquire. It is sufficient to say that for the first half hour there is hardly any appreciable effect: after this, the acceleration goes on increasing for three hours, and then it gradually declines.

Similarly, the intellectual centres, because they are more highly organized and the last to be formed, are readily affected by alcohol. Occasionally, however, it is the lower centres in the brain, those concerned with muscular co-ordination, which are more quickly touched; hence, in alcoholic intoxication the difficulty of standing straight or of walking. Dodge and Benedict, in fact, incline to the view that it is the centres regulating simpler muscular movements which are more severely affected, rather than the intellectual, since even if a man is slightly intoxicated he can yet, under the influence of the will, pull himself together and for a brief period hold mastery over these centres.

Physiology speaks with a somewhat divided voice upon the question whether alcohol increases or diminishes the capacity for work. It does not follow, because of the slightly increased pulse rate which occurs during muscular work and is believed to be a necessary accompaniment of it, that, therefore, any increased pulse

rate consequent upon the ingestion of alcohol means greater capacity for doing work, and this statement is made, notwithstanding the fact of the extra work obtained by the action of small doses of alcohol upon excised muscles and the recuperation of a failing heart in perfusion experiments. Work carried on at an even pace, under normal conditions, may be unattended by any such rise of the pulse rate as to call for special comment, for, as Prof. H. M. Smith has experimentally demonstrated, a man's muscular metabolism during a long walk may be increased $2\frac{1}{2}$ times without his pulse rate being increased at all. We get little assistance, therefore, from a study of quickening of the beat of the heart and its relation to muscular activity.

A much more disputational problem is whether alcohol is a food. What is a food? Is it a substance which merely sustains and nourishes the body, and is capable of being assimilated by it; is it something which, under the influence of digestion, is only capable of repairing the wear and tear of the tissues, or does it also include other material which, without becoming incorporated, can supply energy, and by so doing thus spare the tissues? Alcohol is not assimilated, and it does not enter into the composition of the tissues, and on these terms, therefore, it cannot be regarded as a food, but if it is capable in the body of supplying energy, and of thus saving the tissues from breaking up in order to supply energy, then it is a food, but of an indirect kind, for when alcohol has been absorbed only about 5 per cent. of it is eliminated from the body as such, the remaining 95 per cent. being retained in the body to undergo combustion and be made use of. So slowly is the oxidation carried out that, as we have seen, traces of alcohol are still in the blood 24 hours after it has been taken. When alcohol is undergoing combustion in the body, it gives up energy and thus becomes, technically speaking, a food; but while we accept this as a physiological fact, there are few of us who would say that it is a desirable food under all circumstances, and one to be recommended. It may save the carbohydrate in our tissues, also the fat, so that these remain as reserves of energy; but alcohol is foreign to the body; it can never become part of the tissues or stored up in them so as to be called upon to meet requirements in the same way as carbohydrates. Physiologists

have found an increase of fat in animals to whom alcohol had been given, and the same thing has occurred in man. A few years ago, probably more than in these days, men who worked as labourers in the London docks used to consume large quantities of stout. Most of them were well nourished, and were capable of doing a large amount of hard physical work, but this circumstance was not altogether owing to the presence of alcohol in the stout, but was probably and more likely the result of the large amount of carbohydrate the liquid contained. These men were not only paying extravagantly for the energy they required, since more energy could have been obtained and a larger reserve secured from selected foods, but they were running the risk of injuring some of their internal organs by excessive stimulation of their eliminating functions.

Into the personal, familial and social aspects of this question I do not propose to enter, for the personal and social effects of the abuse of alcohol are known to all of us.

I have incidentally introduced the question of "alcohol a food," because it is an opinion expressed by some working men that alcohol supplies energy, an opinion which, notwithstanding what I have just said, must be received with some qualification, since we must distinguish between the immediate and remote calls upon the energy producing activities of spirit. Alcohol might supply energy for a sprint, but would it evolve the energy required for a long distance race? The stimulating but fleeting effects of alcohol are shown in the "doping" of greyhounds in coursing matches. Owners of racing dogs have told me that it is not an uncommon practice to give dogs light alcoholic stimulants, e.g., champagne, before a competition, but the owners have to know pretty accurately the time the start will take place so that the requisite amount of dope may be given to the animal in order that the stimulating effects may come into operation at the particular period it is required, for, should anything occur to delay the starting of the race, the exciting effects of the dope will have passed away, and these will be followed by a languor whereby the animal's efforts result in failure. The experience which I have just given may be crude, but it cannot altogether be ignored when taken in conjunction with other facts. No boxer or football player ever trains upon

alcohol. It is, in fact, the one thing to be avoided. The trainer of the Newcastle United League Football Club has had 40 years' experience of footballers, and he tells me that few players are of any real value to their club after 10 to 15 years' service, but there are men in his club, as probably in other clubs, who at the age of 40 are still playing an excellent game, and the majority of these men are total abstainers. The trainer does not say that the man who takes a glass of beer occasionally is not as good a football player as an abstainer, but, taking two men who began as professionals at the same age, the abstainer will probably be found in better physical condition at the end of 15 years than his confrere who has used alcohol immoderately. Trainers of footballers, who often become abstainers themselves, so as to be an example, discourage, as far as possible, the use of stimulants, for they have observed that after 20 minutes' play in a match, the men who take alcohol rather freely cannot compete in endurance with the others.

Science has been invited to give expression of her experience in regard to the relationship of alcohol and muscular work. Rivers, in his monograph, tells how Lombard, by means of the ergograph, found that alcohol primarily increased the amount of muscular work done, and that this continued for a short period. Rossi similarly observed a slight increase, followed by a fall. Frey, on the other hand, found a primary diminution of work done, but if alcohol was administered after fatigue had set in, that it had a decidedly beneficial effect. According to Frey, alcohol has a peculiarly double effect: (1) it acts injuriously upon the nervous system and diminishes work; (2) it acts as a muscle food and is, therefore, helpful. Other physiologists have found that while alcohol has no special influence upon healthy muscular fibre, it is capable of whipping up tired muscle so that it becomes capable of doing extra work, but the period during which this continues is short, it is followed by a fall and the decline is always to below the normal.

In a matter of the serious importance we are discussing to-night I am of the opinion that the results of physiological experimentation upon animals, however interesting and valuable they may be, must be considered in the light of, and along with the facts of, human experience. It may, therefore, be not out of place if I mention the experiments

carried out by two American physiologists, Atwater and Benedict, upon themselves. We have dealt mainly with experiments upon animals, let us take man himself. Atwater and Benedict allowed themselves to be shut up in closed chambers, which might be spoken of as large calorimeters. The heat produced was regarded as a measure of the energy obtained from the foods supplied. After a few days' experimentation with food, alcohol was substituted, when it was found that the heat produced was not influenced by the change of diet. The effect of alcohol upon work was then studied. Part of the experiment was that the two physiologists had to turn a dynamo which fed an electric lamp, the heat produced being a measure of the work accomplished. The amount of work remained the same, whether food, or alcohol, was the diet. The results obtained aroused a good deal of interest at the time, and gave rise to considerable discussion, especially in France, a wine producing country. It was pointed out, however, by Rübner that production of heat is not an end in itself, but an incident of life, and that the value of food rests not alone upon the heat which is liberated, but upon the extent to which energy set free can be made use of in vital processes. Physiologically speaking, alcohol is a food, but as Atwater, who was the subject of the experiment just mentioned, reminds us it is a bad food and an undesirable one, and to these words may be added those of other physiologists, that while alcohol in small quantities can undergo combustion in the body, in larger doses it does so to the injury of the body itself.

Many of us are familiar with Dr. Vernon's work upon this subject. Professor Edgar L. Collis, too, in "The Health of the Industrial Worker," has written a helpful and instructive paper upon "Alcohol and Work," but the question bristles with difficulties owing to the conflict of opinions and the absence of uniformity in the results of experimental physiology. It is the subject of alcohol and industrial efficiency which particularly calls for our consideration to-night, and it is upon the relationship of these two that I find it almost impossible to obtain information from managers of large works, both in this country and the United States of America. I can get plenty of opinions, but I can get few details of experience, for data have not been collated. The present attitude of the public mind

towards alcohol is an illustration of the changing circumstances of time, and of the march of an increasing number of the people towards sobriety. By improving the conditions of labour and making trades more healthful, industrial hygiene has encouraged self-respect among the work people and by widening their outlook, has caused them to take a greater interest in movements which tend to make life fuller and occupation freer from sickness and accident. The trend has been in the direction of the preservation of the working classes.

So far as industry and alcohol are concerned, there are certain occupations which, if they do not predispose, certainly encourage persons employed in them to take alcohol to excess. This remark applies particularly to persons engaged in the manufacture and sale of alcohol. Previous to the war, it was found in Munich that at the age of 20, the life of a person engaged in brewing beer was 22 to 38 years, while that of the average individual otherwise employed was 42 years. In pre-war England the mean expectation of life at 25 was 36.1 years, and in publicans it was 31.3 years. In Prussia, taking all the alcohol industries together, the expectation of life of individuals at 25 years of age was, for the average male population, 32.08 years, and that of those engaged in the alcohol trades 26.23 years.

Here the kind of work is responsible for the shortened working period of a man's life. There are, however, certain trades and conditions under which labour is carried on which create a desire for stimulants. Too long hours, working overtime and Sunday labour, also over-speeding, by producing fatigue, create a desire for stimulants. Hard physical labour, such as the puddling of iron and work carried on in overheated atmospheres, have a similar tendency. In some of the large glass works on the Continent, I have seen the men who were working at the furnaces consume in the factory large quantities of alcoholic drinks to replace the liquid lost by perspiration. Men employed in glass works across the Border drink large quantities of beer. The practice of beer drinking was introduced into Scotland, Professor Glaister informs me, by men from England when they went North to establish the industry, and while in these works for many years there is no difference in the output or in the physical fitness of the

two sets of men, drinkers and abstainers, yet, at the end of 15 or 20 years, the alcoholic workmen cannot compete with the men who abstain—at any rate, when at work. This circumstance has been recognised by the men themselves, with the result that workmen who were in the habit of consuming beer in the factory, have taken to the "oatmeal and water" drink of their comrades and with satisfactory results.

Dusty occupations by causing dryness of the mouth and throat also encourage intemperance. There is one trade in particular which is apt to cause the men to become intemperate; I refer to the making of mill-stones for the grinding of cereals, etc. Mill-stone building is a special trade and is carried on in few places. In chipping the hard "buhr" stone fine dust is given off and this is inhaled. I have visited the works on the banks of the Thames and at Ferté Sous-Jouarre in France. The habits of the workmen are the same in both places. The majority of them drink to excess. After they have followed the occupation for a few years they suffer from hemorrhages from the lungs and have but a short life thereafter, many of them being carried off before the age of 40. I was much impressed at the time of my visit by the death at a comparatively early age of these millstone builders, both in London and in France, so that in order to refresh my memory and to be accurate in regard to facts, I recently wrote to the town's doctor at Ferté-sous-Jouarre for information, and he reminds me that while all the workmen are more or less exposed to dust, it is the men who build up the millstones by putting the wedge-shaped pieces of stone together who suffer most, owing to the fact that their work is more fatiguing, that they receive the largest wages and drink most. Many of these men when the value of the franc was high could earn 600 to 800 francs per month, and they drank from 7-8 litres (1½ gallons) of red wine daily. There is a history of alcoholism in 90 per cent. of those who die from tuberculosis of the lungs. Men are attracted to the occupation because only a short apprenticeship is required and they are soon in receipt of large wages, which they unwisely spend in drink. Some of these men work for 19 days and during that period they make 400 francs; they take their wages and drink till their money is gone and then resume work again. It is the men who drink largely who die young.

For years there have hovered round this question of the abuse of alcohol by working men, the incidents of accidents in factories, irregular time-keeping, diminished output and imperfect workmanship. It is pointed out by nearly every writer upon the subject that the largest number of accidents happens in factories and shipyards on Monday, and that this is largely the result of alcoholic indulgence on the part of the working man at the week-end. The practice of week-end drinking is not confined to one country. When we examine the 25,295 accidents which occurred in the high building trade in Berlin a few years before the war, we find that most of the accidents occurred on Monday, viz., 18.7 per cent., as against 15.6 on Tuesday, and 16.6 on Friday, and when we add to these the statistics of German Trade Union Associations, with a membership of 400,000, these also show that the number of accidents declined as the following days succeeded each other, Tuesday, Saturday, Friday, Wednesday, Thursday, Monday and Sunday—the largest number of accidents on Tuesday being explained by the circumstance that the bulk of the men did not return to work until Tuesday.

Mr. H. J. Wilson, H.M. Superintendent Inspector of Factories, dealing with this subject shortly before the war, has no doubt whatever as to Monday being nearly in every instance the accident producer, and next to it is Tuesday. Taking accidents in shipyards, he supplies the following percentages:—

Monday,	24.2 per cent.
Tuesday,	19.0 "
Wednesday,	15.1 "
Thursday,	15.0 "
Friday,	15.2 "
Saturday,	11.1 "

At this date the men were working 9½ hours daily, except on Saturday, when the hours were 5½.

The general consensus of opinion, on the whole, is that Monday is the day of the week on which the largest number of accidents occurs. In the Zurich Building Trades, 1900-1906, the accident rate on Monday was 22.1 per cent. as against the average of 15.7 per cent. for other days—that is 3 to 2, and as regards accidents generally to abstainers and non-abstainers in the iron and steel works at Volklingen there were 8 per 1,000 in abstainers and 12 in non-abstainers—that is in the ratio

2 to 3—whereas the Leipzig Benefit Society found only one accident in abstaining workmen to three among men who were alcoholic.

Since May, 1914, when the public-houses have not been opened until 10 a.m., there is a feeling that there have been fewer accidents on Monday, but the conditions under which, during and since the war, labour has been carried on, do not enable us to speak definitely in regard to this. On the Clyde there was no evidence that drinking had increased during the war. It was practically the same men who frequented the public-houses then as before the war. There was evidence, however, that a number of small bottles of whisky had been consumed off the premises especially by men engaged on the night shift; but, after all, the practice was confined to few men since in one shipyard employing 10,000 men, only three men on one night were found partially intoxicated and had to be expelled from the works.

Irregular time-keeping, and many employers consider this equally important as the question of accidents, is largely the result of drinking, but this occurs also among total abstainers. Lost time is met with in some trades more than in others, e.g., among rivetters, caulkers, platers and riggers and to a less extent in engineers. In shipyards it occurs more frequently in men employed on outdoor work and exposed to the weather. The details of irregular time-keeping require to be sifted, for the mere mention of lost time and of the number of men involved is not enough. One circumstance, for example, which causes irregular time-keeping is group working; riveters work in squads so that if one man fails to turn up at 7.30 a.m. the squad cannot commence work. Four or five men, therefore, lose a morning's work, or it may be a whole day's. Riveting is hard work and the men are exposed to the inclemency of the weather. There are, therefore, several inducements for the men to take a day off, especially as the pay is large and it enables them to do so. For some reason, riveting and plating are not attractive occupations, and as a result there is always a shortage of this class of workmen, a circumstance which causes the wages to be high, and as the men know that there are few other workmen to take their places, there is no stimulus to them to put forth their best exertion.

"Lost time" in industry is a serious matter and one which can only be restituted by the working men themselves. That it can be improved has been shown by the action taken in some large factories of which the following may be mentioned :—Messrs. Creed and Co., engineers, at Croydon, three years before the war were employing 150 men, and in consequence of lost time they made total abstinence a condition of employment. The average lost time in the engineering trades generally before the war was about 10 per cent., but in Messrs. Creed's works it fell to half of one per cent., and while, during the war in the average engineering shop, "lost time" rose to 15 per cent., in Creed and Company's works it was from 1 to 2 per cent., in 1917, and 5 per cent. in 1918.

There is more irregular time-keeping in the shipbuilding industry than in such trades as engineering and iron and steel making. Several circumstances may contribute to this. It may be that exposure to severe weather in winter with rain and high winds has something to do with the greater loss of time. It is hardly right to have men working in their wet clothes and catching cold through hanging about afterwards, for this circumstance of itself tempts the workman to take alcohol.

One large firm on the Clyde took a vote from the men as to whether in their opinion there should be further restrictions placed upon the sale of alcohol. Mr. H. J. Wilson has sent me the following figures of those voting in favour of restriction :—

	per cent.
(1) Are you in favour of total prohibition?	31
(2) Are you in favour of leaving matters as they are	44
(3) Are you in favour of reducing the hours to from 12 noon till 2 p.m. and 7 to 9 p.m., and on Saturdays 6 to 10 p.m.?	11
(4) Are you in favour of reducing the hours from 7 to 9 p.m. on weekdays and on Saturdays 6 to 10 p.m.	4
(5) Are you in favour of leaving the hours as they are, but for the sale of beer only?	10

Out of 2,500 men two-thirds voted.

Following up my enquiry it seemed to me that it would be helpful if I could ascertain the opinions of large shipping firms in regard to the part which alcohol

plays in the life and work of the British seaman. I accordingly wrote to Sir William Noble, a well-known North of England shipowner, who is interested in these problems and who as Chairman of Societies connected with shipping has been able through the Manager of the Shipping Federation to obtain for me the information I desired. I asked Sir William Noble whether a few years ago it was a common event for ships to leave ports in this country with some of the sailors not in quite the best state of body and mind for the voyage as a consequence of drinking, whether his own office or associations had any data regarding inefficiency of service on the part of seamen from alcohol, also after a drunken bout, as to how many days were required before the affected men could undertake full work? Sir William Noble, in his reply, stated that there was less trouble now than in former days. It is still, however, an unfortunate fact that men on going to sea join the ship under the influence of drink. Two or three days might elapse ere the men were quite themselves again and fit to take up their duties. Unfortunately, however, the difficulty arises on each occasion the ship reaches port and when the men ask for money on account of their wages.

Mr. Havelock Wilson, writing to Sir William Noble and acknowledging the receipt of a copy of my letter which had been forwarded to him, says: In the old sailing ship days such cases did happen, but in the days of steamships it is very rarely that sailors go on voyage with their health affected by drinking. Such cases are more often to be found among firemen. My experience of many years is that the men of the mercantile marine have improved very much with regard to drinking habits. I do not mean to say that there are no cases where crews proceed on voyages in a drunken condition, but taking them generally I think they will compare favourably with any other body of men.

Mr. Cuthbert Laws, General Manager of the Shipping Federation, London, very kindly took up the matter and wrote to Technical Advisory Committees and to several of the large shipping offices of this country, asking them to give an expression of their opinion upon the questions raised in my letter, and which for simplicity he classified thus :—

- (1) Was it a common occurrence a few years ago for ships to leave ports—

- (a) in this country, and
 - (b) abroad,
- with seamen either wholly or partially incapacitated as the result of drink ?
- (2) How does the present position compare with the pre-war position ?
 - (3) Can you give any estimate of the amount of time lost by seamen in consequence of drink and the degree to which the efficiency of their service has been impaired from this cause ?
 - (4) Has it been your experience that total abstainers do better work and give more efficient service than men who drink freely—
 - (a) during the period when men are sober ?
 - (b) taking the service as a whole ?
 - (5) Have you any general observations to offer on the subject of alcohol in relation to employment at sea ?

The questions which the General Manager of the Shipping Federation drew out, and to whom I take this opportunity of tendering my thanks, quite cover the ground I had in view. Forty-eight shipping firms replied to Mr. Cuthbert Law's questions, but not all of them directly and to the point.

In regard to No. 1 (a) 43 replied yes, and to (b) 41 gave an affirmative answer.

In regard to question (2) 38 stated that the position was better, 4 that there was no improvement, and 1 that things were worse now than formerly. As to question (3), it was affirmed by 33 that time was lost, 15 stating that this was equal to one day or part of a day, 6-8 hours, and five that it was one to two days or even more. Question (4), which asked whether abstainers did better work was answered thus: (a) 17 yes; 18, however, stated that if the work done by men who took alcohol was not better, it was certainly as good as that done by abstainers, while a few thought that the work was better; and in regard to (b) 25 replied "yes" and 10 "no."

Some of the remarks made and the suggestions offered by shipping firms are interesting and call for notice. There is the opinion that as a class seamen are well behaved and compare favourably with men in other occupations. Opinions are divided as to whether alcoholic drinks should be taken to sea and sold by the captain of the ship to the men, for there is a feeling that it is the deprivation of stimulants during a voyage which is partly responsible for the men breaking loose when they reach a sea-

port, and then even in port, particularly abroad, it would be safer and better for the men if stimulants were procurable on board of ship instead of in the public-houses. Against the sale of alcohol on board ship, either during a voyage or in port, many owners are of the opinion that alcohol should be served out as a medicine and only under necessitous circumstances. There is not the least doubt that men who in port exceed the limits in regard to the use of alcohol, once the effect of a debauch has passed away, are good workers and are in no way inferior to abstainers. But it is just the debauch in port which not only causes loss of time, but may interfere with the safety of a ship—so much is this the case that some of the shipping firms maintain that no man should be allowed to proceed upon a voyage who is under the influence of drink. Those who know that it is these men who do not turn up until almost the last moment before a ship sails, can appreciate the difficulty of giving effect to this recommendation. As a consequence of allowing firemen to proceed to sea who have been drinking too freely, considerable damage has occasionally been done to the boilers of the ships, and as a result of seamen not arriving in time to sail with the ship, coloured labour has frequently had to be resorted to instead. It is an open question whether the stopping of advanced pay to seamen would diminish the amount of drinking when a port is reached. Of all occupations that of going to sea is one particularly in which total abstinence has its advantages, for whether abstainers are better workers or not, they at any rate are more reliable under all circumstances. It is worth considering whether stoppage of advanced pay, not only to seamen, but to men employed in other occupations, would diminish drinking. There is not the least doubt, as a large building contractor on Tyneside writes to me, that previous to the war alcohol was the cause of much lost time through week-end drinking. Since the war this has been less noticeable owing to there being fewer opportunities of obtaining alcohol, and that the younger men are seeking relaxation in other directions, such as sports and entertainments. In the building trade it is difficult to ascertain the amount of industrial inefficiency caused by alcohol since no reliable data are available and many of the workmen are only casually employed. From general

observation the loss to the workman in days off through alcoholism 15 to 20 years ago could be estimated at one day per week per man; immediately previous to the war this was considerably less, and since the war the loss has been almost negligible. The loss of time through sickness is to the abstaining workman about half of that lost by the alcoholic. I had asked this contractor how far he thought what is called "subbing," that is, payment of part of the wages to the men in the middle of the week, was a real help to the men themselves, what was the type of the men who asked for it and whether "subbing" had any influence upon the character of the work done by the men in the latter half of the week? In the building trade "subbing" is largely a personal matter; it is made use of mainly by the unskilled men. It is asked for regularly by men who, having earned the wages, claim the right to a large part of them, while occasionally the request has to be made by men who have been out of employment, and who with their families are in need of sustenance. Men, as a rule, do not lose a day's work after "subbing," although in a few instances it is clear from the manner in which the work is done that they are not quite clear from the effects of alcohol.

Another large contractor states that conditions since the war have materially changed for the better. This contractor has always been opposed to the practice of giving "sub" to the men unless in exceptional cases, such as a man having been out of employment for some time, but when labour is difficult to obtain, men frequently refuse to work for a firm which does not give the mid-weekly pay. His opinion is that men who "sub" regularly are not so efficient in their work, a circumstance for which he thinks alcohol is to some extent responsible.

I am informed by one of the under managers of a large shipyard on Tyneside, and who has had considerable experience of the Clyde, that many riveters employed there do not commence work until Wednesday morning, when they ask to be supplied with 1000 rivets. These men work their hardest for the next $3\frac{1}{2}$ days, and the work is by no means light. Since several of the men have already consumed the wages of the previous week, they are obliged to be paid their wages wholly or part in advance, on the understanding that they will give

adequate service in return. This system is called "flogging dead horses." Unfortunately, when Saturday afternoon comes, many of the men resume drinking, with again lost days of work in the following week, and as a result of hard work and hard drinking continued over a lengthened period, these men, after 15 to 20 years, are physically speaking done.

To bring this lecture to a close we will ask the question what benefits do working men expect to get from alcohol, and what do physiology and industrial experience promise them? It is generally admitted that the sub-division of labour and the multiplication of machinery have made present-day work monotonous and in certain quarters there is a feeling that alcohol by paralysing the critical faculty blunts the senses to the influence of monotony. The remedy, therefore, is not to denounce alcohol solely, but to widen the interests of the working classes by making work more congenial, if such is possible. While admitting that monotony of work may be a cause of drinking, if this were the serious cause which has been advanced we would expect to find drinking more prevalent among indoor workers shut up all day amidst the noise of running machinery in textile factories, whereas if drinking is not more prevalent, certainly its effects are more apparent in men engaged in the harder trades in which they are exposed to high temperatures or to the severity of the weather.

Although I have dealt at considerable length with it, the question of alcohol being a food hardly concerns us, for while physiological experiment shows that it can be ranked as such, it is only indirectly by sparing tissue, to the building up of which it cannot contribute. No one would recommend it as a food on account of its costliness; besides, two ounces of pure alcohol is stated to be the limit which can be burnt up in the body without harm in a day. It is impossible to say how long it takes for alcohol consumed in larger quantities than I have mentioned to produce structural changes in the body. The effects are functional at first and are primarily seen in the loss of co-ordination of nerve centres in the brain. It is in consequence of frequently repeated functional derangement of brain and liver without sufficiently long intervals of abstinence for recovery to take place, that week-end drinking, with all its

objections, is less harmful than constant sipping. And yet, so far as the man who uses alcohol sparingly and in moderation is concerned, neither experience nor physiology shows that he is an inferior workman to the abstainer. Although the question is mainly a personal one, in the Western Hemisphere it is being made a race problem. A few years ago, had I asked myself whether abstaining nations or peoples had done more work and better, and had contributed in larger measure to the cause of civilization than those using alcohol, I should have felt inclined to answer *No*; to-day the answer must be withheld for a large, vigorous and prosperous nation has taken upon itself the task of making its people sober. An experiment on a gigantic scale is being carried out by the United States, and the civilised world looks on, awaiting with patience the results, for by many persons it has been held that those nations have been the most progressive whose people have been proteid consumers, largely of meat, and who have not denied themselves the luxury of alcohol. It cannot be said of the Mohammedan races of Asia and of Eastern Europe, for example, that total abstinence has raised them to a higher plane of civilisation, given them a prominent place in the industries of the world or conferred upon them those practical qualities so characteristic of the men of the west.

The drinking habits of a nation change. It is so in this country, and many thoughtful members of the industrial classes are asking for guidance in regard to the subject. Whether alcohol is taken by working men to-day to minimize the effects of monotony and dispel the sense of fatigue, or not, it is evident that drink is consumed less for the sake of conviviality than it was years ago. Even admitting that it is taken to dispel the sense of fatigue, it is doubtful whether fatigue is really dispelled, for it may be as Professor Cathcart and many of us believe, that the sensory centres in the brain are simply benumbed so as to be less influenced by the conditions which create fatigue. It is in consequence of this peculiarly paralysing action upon the higher and psychical centres in the brain that alcohol has ceased to be considered a stimulant and is now regarded as a depressant. Alcohol does not increase the resistance of the body to disease; too often it paves the way to such a disease, for

example, as tuberculosis. When taken to the point of interfering with the operation of co-ordinating nerve centres in the brain, alcohol tends to impair efficiency, intellectual and physical, so that no man who has important work to do is acting in the best interest of the work, nor is he doing the best for himself, by undertaking work upon alcohol.

DISCUSSION.

The CHAIRMAN said he should like to congratulate the Council of the Royal Society of Arts on having such a paper read just at a time when it was very difficult for men to get work, and when it was most necessary to get the maximum output with the minimum effort. Those present had listened with a very great deal of instruction and pleasure to the paper, and had got the very thing they wanted in a paper upon such a subject, and that was, facts. The arithmetical argument appealed to other people, as well as to themselves. The learned physiologist said that this question of alcohol might be dealt with from four aspects, but he was going to leave out the ethical. He himself found it most difficult to keep his temper when discussing the effect of alcohol, because of all substances in nature, it was the one which had the most far reaching consequences. Human energy was too valuable to be mis-used or wasted: in the vast field of human labour it needed careful supervision, and should be fostered in the most special way possible. The first thing for anyone to do if he wanted to keep well, and do the best work, was to guard against the enemies of the body, and he maintained that there was one enemy in particular which could so delude the reason as to give, when taken to excess, the feeling of increased happiness, well-being and comfort, and it was the effect of the excess in regard to this enemy that was the subject of the paper they had just heard. Alcohol came from a bad family, being allied to naphtha, benzine, kerosine and petrol, which nobody would think of drinking. They had abundant proof of the effects of alcohol upon living tissues, and he could confirm that in his experience, which was very extensive amongst working people and the industrial classes. If a plant was watered with alcohol, in a very diluted degree, it soon curled up, withered and died. Creatures in the lower scale of life, like tadpoles, died at once when dropped into much diluted alcoholic solutions, and the experiments carried out on the Canadian trapper and hunter, Alexis St. Martin, who went to live with Dr. Beaumont, the physiologist, proved most conclusively that alcohol paralysed the nerves of sensibility and irritated and inflamed the gastric mucous membrane. Alexis had

the front part of his body wall blown off, leaving a little window which permitted the physiologist to look into the stomach during digestion, and see what went on when alcohol was administered. The liver got hard, and, like a carter's boot, "hob-nailed," and the brain shared the same fate when drinking was habitual and long continued. As Sir Thomas Oliver had said, the highest tissue was first affected, because it was the last formed, the least organised, and the least fixed, and the mental effects of long continued alcoholic excess were (1) a difficulty in fixing and concentrating the attention; (2) an impairment of memory, and (3) a perverted, deflected and oblique moral sense. The memory, reason and judgment, being the highest faculties of man, were affected. A man who indulged a long time in alcohol, was on the borderland of insanity; and when he was the Medical Officer at Claybury, 20 per cent. of the men and 10 per cent. of the women patients were certified to be insane because of drink, many of these being high class workers. The insurance companies knew this, and realised that the person who drank was not a good "risk"; that 51 non-abstainers to one abstainer died between 21 and 30 years of age, or, in other words, the deaths were 50 times greater. Also, at 20 years of age, a temperate person had the expectation of living to sixty-five and one-fifth years, while the non-abstainer would only live to 47½ years. Alcohol deserved the name of deceiver. It made a man think he was happy, and yet he became more wretched. It soothed pain because it paralysed the nerves; it relieved hunger because it soothed the appetite; it removed the feeling of cold because it dilated the vessels of the skin, and so gave a false sensation of warmth, whilst in reality it lowered the body temperature. The war gave us an opportunity of controlling the consumption of alcohol, and for this first movement in restriction and reconstruction, we owed special thanks to the trade unions, which called the attention of the Government of the day to the delay in transport, great slackening in making munitions, and to ill-health owing to excessive drinking amongst the workers. Thanks to the Board of Control (Liquor Traffic), and to Lord D'Abernon in particular, special restrictions were made after a request had been presented by the local authority, and by means of these a vast change occurred, so that the whole country practically came under restricted orders, but the trade unions, which were originally mainly responsible for establishing restrictions, later clamoured loudly for more drink, and so the Licensing Act of 1921 was passed, extending the hours of sale, and permitting the Licensing Justices to exercise a discretion, and, as a result of this, they had been bombarded with petitions to extend those hours, and counter petitions not to do so. The result of Lord D'Abernon's administration was less consumption of alcohol—a decline of

18 per cent. in 1918 compared with 1917, or of 60 per cent. as compared with pre-war consumption in 1913. Another result was less crime; crimes of violence in 1919 were 71 per cent. less than in 1913. Juvenile crime in 1918 numbered 27,787 instances, while in 1913 it was just under 150,000. In addition there was more work got through, there was greater order in the streets, and on railway platforms, more money was placed in the Savings Bank, and there was greater contentment. He was informed soon after the Welsh Sunday Closing Bill became law, that in the slate quarry districts the men then went to work on Mondays. The effect of alcohol was experimentally ascertained by very careful observations made (1) by testing the memory, and (2) by recording the influence of alcohol on manual work and neuromuscular co-ordination, and much information was gained in regard to the effects of alcohol taken concentrated or diluted, and also without food and with meals. The method adopted by one observer, Dr. Vernon, was with typewriting, when speed after alcohol was delayed, and lessened accuracy was displayed, the quality and the quantity of the work being definitely affected. Another method was the so-called "target method," which meant pricking a certain number of marked spots at a given distance in a given time, which showed that, after alcohol, three times the number of errors were made as compared to those made when not taking alcohol. The scientific committee appointed by Lord D'Abernon furnished the Board of Control (Liquor Traffic) with a report that should be in the hands of every person interested in temperance, and especially of those who were interested in increased production in industrial enterprises. The results of Prohibition in America were not being fairly dealt with in the Press. There was so much propaganda in order to influence Great Britain, that the Press in America did not give the present legislation a fair deal. Those results were diminution of industrial accidents, better time kept, better home conditions, better health, fewer admissions to hospital, the acquisition of the saving habit, fewer bad debts to tradesmen, homes were purchased, luxuries formerly unknown to the family in the shape of clothes, food and holidays, were obtainable under the present circumstances, there was less destitution, greater content and happiness, and increased laundry bills, indicating that there was a greater feeling of self respect.

MR. W. MCADAM ECCLES, M.S., F.R.C.S., remarked that, like the rest of those present, he had been intensely interested in Sir Thomas Oliver's paper, coming, as it did, from such a centre as Newcastle-on-Tyne, which, as they all knew, was a very hive of industry. There were one or two points he should like to allude to in connection with his paper, rather in the way of elaboration, and not of criticism. Sir

Thomas had alluded to the point of team work and had said that, if one of the teams was incapacitated, or for one reason or the other did not put in an appearance, there was a failure in efficiency, because the whole of that team was thrown out of gear. The speaker said he did not know, of course, the ins and outs of shipbuilding, but he did know what it meant in the team work in his own profession of medicine, and he knew that if there were in a team one or two who were not up to efficiency, particularly through alcohol taken in the middle of the day, it was a very serious matter to the smooth running of that team's work. Then, in regard to accidents in factories, there was one matter which he did not think Sir Thomas had alluded to—it was one of exceedingly grave import—and that was that the consumption of alcohol—not necessarily when the consumption was sufficient to make a man a drunkard—was apt to have the effect of dulling the sense of danger, and, further, these men were very apt indeed to disregard accident warnings. In fact, it was well known that when the first warning was put up on Monday morning, it was far more apt to be disregarded than if the warning occurred later in the week. Then there was the fact that the alcoholic worker—and, again, he was not alluding necessarily to those who were habitually under the influence of alcohol—was a danger to his fellow workers, a very important point. Passing on to the point of health, Sir Thomas had said that alcohol was the direct cause of disease. That they all knew, and while alcohol was an indirect cause of disease, the inefficiency due to alcohol was the result of its preventing the natural functions of the body being carried out to their best effect, particularly in connection with digestion, and directly there was a failure of proper digestion, they got inefficiency in the workers, who could not then put out the utmost of their strength. Sir Thomas alluded to the question of fatigue. He himself was always prone to put it in this way, that alcohol was a narcotic, and, therefore, fatigue was covered but not removed, or, to put it a little more scientifically, fatigue was due to waste products in the muscles and other parts of the body, or what might be called—and he thought Sir Thomas would agree—poisoning, and until this poison could get out of the body, it interfered with labour. Alcohol dulled the sense of fatigue, but it left toxin in the body, and still further time was required to eliminate the fatigue products. This was a very serious question in the matter of efficiency. The last point he would allude to was this, that if alcohol was really a disadvantage to the industrial workers and to the efficiency of our nation, which was absolutely necessary at the present time, these facts concerning alcohol should be kept before our workers continually.

MR. GEORGE B. WILSON (Political and Literary Secretary, United Kingdom Alliance), said he had been very pleased to hear what Sir Thomas Oliver had said about America, and he certainly thought that a great duty devolved upon this nation in keeping an open mind on the question of America. He thought that Sir Thomas would agree that they could not expect to see the general results of prohibition in America, whatever they might be, exemplified conclusively for a number of years, and he should be very much obliged if Sir Thomas would tell them what were the directions in which they must look for evidence which would be useful for this nation. He remembered talking a couple of years ago to Professor Irving Fisher, when he was over in the States, and he made some very strong statements about the effects on the ground of efficiency that the coming prohibition would bring about, and he further said that he would be very much surprised if prohibition did not result in an increase in America of something like 30 per cent. of the general efficiency of the nation. He said he was pretty certain it would be 20 per cent., but he was prepared to stake his reputation on 10 per cent. When they thought of America with its unlimited natural sources, its immense man power, and the other great advantages, which it had in contrast with us, and especially when we considered the loss of so many of the finest of our young men, we could see the possibility of America beating us in the industrial race, and he thought that our leaders of industry, both employers and leaders of trade unions, had not sufficiently realised the importance of asking themselves this question: "Supposing America is going to gain a ten per cent. increase of efficiency as the result of prohibition, can we afford to give her such a start in this age of industrial competition?" It seemed to him that the answer to that question ought to determine the attitude of our own nation on this great question of alcohol, and if the evidence that had been brought forward that evening was, as they believed it to be, thoroughly sound, it seemed to him that there could be only one answer to the question. If this non-alcoholic law put America on far better terms than ourselves in the industrial struggle, this nation must at any rate, seriously consider whether the American action was not an action which could be followed in this country. Therefore, it seemed to him a very unfortunate thing that the issues were not being fairly put to this country, which was not being allowed to consider this matter as a great social and industrial experiment, and he hoped that all those who could get into the Press, when so many were excluded, would take the opportunities which were open to them, from the prominent positions they held, of impressing on the people of this country the need of keeping an open mind on this matter. When

they had got the whole of the evidence before them, let them strike the balance fairly one side or the other. Only in that way could our nation come to a right decision.

SIR GEORGE HUNTER, K.B.E., said he was deeply interested in this question, and particularly in Sir Thomas Oliver's observations. He hesitated to take part in the discussion, because he was not supplied with any special figures or facts, and it was not opinions that were wanted, but he maintained with certainty, that during his experience there had been a great falling off in industrial efficiency through lost time, caused by drinking. Prior to the change of hours by which the starting hour in shipbuilding is now 7.30 instead of 6 a.m., the statistics that had been placed before him showed clearly that the number of men working on Mondays was much less than on any other day in the week, and the number working on Tuesdays had been less than on the four later days of the week; and, of course, the fact that these men were not present to do their work affected the employment in which they were engaged, and their efficiency. In regard to the accidents, where it had been stated that there were more accidents on Mondays than on other days of the week, it was important to remember that these accidents in his experience were not calculated in proportion to the number of men who were at work, and, as the number of men at work on Monday was decidedly less than on any other day in the week, and a larger number of accidents occurred on Monday than on other days, the fact was emphasised that accidents were more likely to take place on Monday than on other days. With regard to the question as to whether abstainers or non-abstainers were more efficient, that might be considered from two points of view. He could say, with absolute certainty, that employers relied more on the abstainers, because they were the better men, taking everything into consideration. They were more reliable, more peaceable, and their example was a great benefit to other men and to the industry. It was often said that in many cases men who drank were better workmen than those who were abstainers, and there were, undoubtedly, many cases of very good workmen who were, at the same time, drinkers. One explanation of that, and he thought an important one, was given to him by a Newcastle physician, as the reason, and that applied in the case of some of the shipowners, who were of opinion that the drinkers were sometimes better than the abstainers. The fact was this, that the clever workman, who was not a drinker, rose to a higher position, and became a foreman, while the clever workman, who was a drinker, did not rise, and although he was still a clever workman, he remained a workman. He thought there was a great deal in that. In regard to the question

of housing, they were often told, especially by those who spoke on behalf of the drink trade, that it was the wretched housing conditions that led to drinking, but was it not the fact that, as far as bad housing conditions were concerned, it was the drink that was the cause, because a man preferred to spend his money on drink, rather than on a good house? In his own experience, he had known men who were capable of earning more than a pound a day, who grudged spending more than three or four shillings a week on their houses, although they had large families.

MR. ALFRED RORKE said that Sir Thomas had referred several times during his lecture to the fact that alcohol was a stimulant, and asked the question why the workman took drink. It was obvious they took it for stimulation. The previous speaker had referred to America, but he did not say how the question of drink in connection with America was to be dealt with, because there was any amount of secret drinking in America, and as long as alcohol was a stimulant, some means must be sought of regulating and administering it. Last week there was a discovery of cocaine being smuggled into this country, and the authorities seized it and took it to the hospitals. Why did they take it to the hospitals? Because it was a stimulant. In regard to the general use of alcohol by the population, and the question of clever workmen and drink, they were up against rather a difficult question, because it was on record that there had been no first class poet, and no first class musician who had been a total abstainer. They were dealing with the question of drink amongst workmen. The drinking habits were not entirely restricted to the working classes, and he had known many managers and proprietors who were terrible drinkers. When it became a question of stimulation, let them take cocoa. Who on earth could drink cocoa for stimulation? A coroner's officer had told him, in numerous cases of suicide, on a *post mortem* examination, it was found that the people were full of cocoa, and when people threw themselves over Waterloo Bridge, they frequently had a drink of cocoa beforehand at the coffee stall at the end of Waterloo Bridge. It really amounted to this. That as long as there were human beings on this earth, they would seek stimulant, and it was the duty of scientists to tell people how they should take it, and how they should regulate it exactly, as in the case of the cocaine which had gone to the hospitals.

MISS ROSE E. SQUIRE (Home Office) said the paper had included many points of great interest, and one that she might mention particularly was in regard to the beneficial effects of factory legislation, and the establishment of welfare conditions on women em-

played in the laundry industry. She believed she was the first woman to inspect laundries, and when she looked back, and saw the difference between the conditions at the laundries, and of the women employed there then and now, she thought she could say that there was a very great difference between the improved conditions of employment and those that existed when the Act of 1895 became law. When she first inspected laundries, beer was brought into them twice a day by potmen, and that was a great temptation to women who were addicted to drink, and who worked excessively long hours in heat and steam. Women engaged in laundry work now-a-days, were a most self-respecting class, and had got a reputation for diligence and sobriety. In regard to men's employment, she was of opinion that conditions had not on the whole improved in the same degree that the conditions of woman's employment had improved. The Home Office Welfare Orders, however, applied equally to men and women, and one of the improvements that had resulted from one of the welfare orders, and one which contributed to the sobriety of the worker was the requirement that pure drinking water should be installed in every factory. Until that order was made, in 1917, even in works where heat was excessive, it was very exceptional to find means of obtaining drinking water.

Mr. A. PATRICK said he did not think there had been any investigation made in regard to the recent boycott of beer by doctors, or as to what the result of that boycott was, as to the results of it in relation to efficiency of the work done by the dockers, but he believed that if statistics were obtainable, it would be found that there was increased efficiency during the time that the strike was in progress. In regard to the medical aspect of the question it was interesting to know that the London Temperance Hospital, during the time it had been in existence, had treated no fewer than 44,020 in-patients, and when certain prescriptions had to be given, they were entered into a book, and then the alcohol had to be administered as a drug, and in its pure form, not in the way of wines, beers or spirits. So far as the question of prohibition in America was concerned, he thought that what evidence was coming from across the water, was more in favour of total abstinence than against it, and he believed that if the evidence on both sides was thoroughly sifted, it would be found that prohibition was going to remain, in spite of what its opponents had to say against it.

SIR THOMAS OLIVER, in reply, expressed his gratification at the general tenor of the discussion. Although the question of alcohol had been thrashed out a great many times, no settlement had yet been arrived at. In regard to prohibition in America, and what the extent

of improved efficiency would be, no one could tell at the present time. Professor Fisher was a very strong advocate of it; and if he thought that it would result in a ten per cent. efficiency, Great Britain, as a country, could not stand out and let America have that start in the race. In regard to what Sir George Hunter said respecting workmen and abstinence, he thought there was no doubt that all round, if one wanted reliability, an abstainer could be relied upon more than a non-abstainer, as he was at work all the time, and was generally a good worker. There was no doubt that in many cases, when men went to work on Monday morning, they had not got rid of the alcohol that they had been consuming on the Saturday and Sunday, and their brains not being perfectly clear, the men did not exercise caution, and the result was an increase in accidents. Sir Thomas gave an interesting statement of his experiences in regard to cocaine, when it first was discovered and used as a drug, and said that in treating a patient who occupied a very high public position in the North of England with cocaine, the patient told him that he was stimulated to such an extent that he felt he could fight the whole council. Sir Thomas said we now knew cocaine to be a deadly poison, and to be avoided at all costs. As Mr. Patrick had observed, there was a great change in the minds of medical men with regard to the application of alcohol, and the profession did not use it now in the way it was used some years ago. It was used occasionally, but the limit which could be consumed in the body in about 24 hours was about two ounces. He did not see the bottles of brandy now-a-days that used to be found in a sick bedroom years ago, and medical men rarely ordered more than from two to three ounces of alcohol during the 24 hours.

On the motion of the CHAIRMAN, a vote of thanks was accorded to the author for his lecture, and the proceedings then terminated.

THE JERKED BEEF INDUSTRY IN BRAZIL.

Xarque is dried and salted beef, known in English as jerked beef. At present the largest amount of xarque produced in Brazil, both for home consumption and for export, is made in the southern and south-central States, namely, Rio Grande do Sul, lower Matto Grosso, and Minas Geraes, where there are 74 xarqueadas. Thirty-five of these plants are in Rio Grande do Sul (although only 26 were operating last year), 27 in Minas Geraes, and 12 in Matto Grosso. Besides these there are others situated in Sao Paulo, Parana, Goyaz and Rio de Janeiro, but their exact number is not known. The 74 xarqueadas have an annual production of over 50,000 tons of xarque.

Although the majority of the xarqueadas are situated in the southern part of Brazil, the

northern sections of the country are great consumers of this product, the xarqueadas having been established in the south because they were pushed out of their original sites in Argentina, Uruguay, and Paraguay, by the packing houses, against which they could not compete, and because cattle can be raised more profitably in the milder climate of the south than in the hot northern States, where large numbers of cattle die each year from the drought. According to official figures, there were 8,918,270 head of cattle in the State of Rio Grande do Sul at the close of the year 1919. This shows a gradual increase since 1915, when there were 7,793,108 cattle in the State. From the year 1915 to 1918 the numbers of cattle killed for the manufacture of xarque were 483,514, 469,327, 667,932, and 535,998 respectively. In 1920, 644,543 head were killed to make xarque. By way of comparison it may be noted that the frigorificos used 352,180, 361,120, 265,000, and 380,000 head, respectively. The exportation of cattle on the hoof in 1915 was 18,235 head; in 1916, 11,250; in 1917, 26,272; and in 1918, 41,454 head; 957,442 head of cattle were used for all of these purposes in 1919.

According to a report by the United States Assistant Trade Commissioner, at Rio de Janeiro, that city is the central distributing point for xarque, and the markets of the north are supplied from there. In the year 1920 281,234 bales, weighing 24,021,690 kilos, were brought into Rio de Janeiro, 61,618 bales of which were re-exported to the north and 223,103 bales consumed locally.

The following figures show the amounts of xarque exported from Brazil during the years mentioned:—

Year	Quantity.	Value
	<i>Kilos</i>	<i>Milreis</i>
1902	63,796	56,137
1909	645,000	314,521
1912	13,981	14,816
1913	20,554	22,182
1914	138,306	135,863
1915	2,265,080	2,164,692
1916	7,121,603	7,555,949
1917	8,728,015	9,830,254
1918	4,809,316	7,296,008
1919	5,556,389	7,699,782
1920	7,889,072	10,213,077

The nominal value of the Milreis is 1s. 4d

During and since the year 1915 the exports of xarque have greatly increased, but contrary to general opinion this was not directly due to the war, for over 95 per cent of all xarque exported went to Cuba, either directly or via Uruguay. Except in 1917, when France bought 394,887 kilos and the United Kingdom 65,440 kilos, shipments to these countries have been very small. In 1916 Spain imported 291,035 kilos of xarque from Brazil, and 100 kilos in 1917, but has taken none since.

GENERAL NOTE.

VICTORIA AND ALBERT MUSEUM: INTERNATIONAL THEATRE EXHIBITION.—The final arrangements for the International Theatre Exhibition, which is to be held at the Victoria and Albert Museum, with the co-operation of the British Drama League, the Actors' Association and other societies and individuals connected with the Stage, are now being completed. The whole of the exhibits from the recent Exhibition at Amsterdam have been received at the Museum, and considerable additions have been made to the British, American, French, Italian and other sections. A dark-room is being fitted up, to contain about 100 lighted models of theatre scenes. The catalogue is now in course of preparation, and it is hoped that the Exhibition will be opened on June 1st or 2nd. Information with regard to the nature and scope of the Exhibition can be obtained from the following members of the Publicity Committee:—St John Ervine, 9, Arcade House, Temple Fortune, Hendon, N W; Ivor Fraser, Electric Railway House, Broadway, Westminster, S W 1; E O. Hoppé, Millais House, Cromwell Place, S.W. 7; Walter Payne, 25, Charing Cross Road, W.C. 2; Horace Shipp, "Theatre Craft," 4, Bloomsbury Place, W C 1; Geoffrey Whitworth, The British Drama League, 10, King Street, Covent Garden, W C. 2; Martin Hardie, Victoria and Albert Museum, South Kensington.

MEETINGS OF THE SOCIETY.

ORDINARY MEETINGS.

Wednesdays:—

MAY 24 (at 8 p.m.)—**GEORGE FLETCHER**, Department of Agriculture and Technical Instruction for Ireland, "The Natural Power Resources of Ireland." **SIR GEORGE T. BEILBY**, D.Sc., LL.D., F.R.S., Director of Fuel Research, in the chair.

MAY 31 (at 3 p.m.)—**LAWRENCE HAWARD**, M.A., Curator of the City Art Gallery, Manchester, "The Manchester Art Gallery and the Problem of Provincial Collections."

INDIAN SECTION.

Friday afternoons at 4.30 o'clock:—

MAY 26.—**SIR THOMAS W. ARNOLD**, C.I.E., D.Litt., M.A., Professor of Arabic, School of Oriental Studies. (Sir George Birdwood Memorial Lecture.) "Indian Painting and Muhammadan Culture." **THE RIGHT HON. VISCOUNT PEEL**, G.B.E., Secretary of State for India, in the chair.

JUNE 23.—F. W. Woods, C.I.E., late Chief Engineer, Irrigation Department, Punjab, "Irrigation Enterprise in India."

Date to be hereafter announced:—

J. T. MARTEN, I.C.S., M.A., "The Indian Census."

DOMINIONS AND COLONIES SECTION

FRIDAY, JUNE 9, at 4.30 p.m.—**MAJOR SIR HUMPHREY LEGGETT, D.S.O., R.E.,** "Tanganyika Territory (formerly German East Africa)."

MEETINGS OF OTHER SOCIETIES FOR THE ENSUING WEEK.

MONDAY, MAY 15. British Architects, Royal Institute of 9, Conduit Street, W., 8 p.m. Mr. J. A. Gotch, "The First Half-Century of the R.I.B.A."

Victoria Institute, Central Hall, Westminster, S.W., 4.30 p.m. Rev E. L. Langston, "The Times of the Gentiles in relation to the End of the Age."

Geographical Society, Kensington Gore, S.W., 5 p.m. Mr. E. A. Reeves, "The Evidence of a True North and South Directive Force in the Atmosphere."

University of London, King's College, Strand, W.C., 5 p.m. Prof. G. B. Gray, "The Place of Sacred Gifts in Hebrew Practice and Thought" (Lecture II). 5.30 p.m. Dr. Don Rafael Altamira, "The Contemporary History of Spain." (Lecture V).

TUESDAY, MAY 16. Statistical Society, at the ROYAL SOCIETY OF ARTS, John Street, Adelphi, W.C., 5.15 p.m. Discussion on "The Scientific Value of Life Tables," to be opened by Dr. M. Greenwood.

Royal Institution, Albemarle Street, W., 8 p.m. Prof. W. Bulloch, "Tyndall's Biological Researches and the Foundations of Bacteriology." (Lecture I).

Photographic Society, 35, Russell Square, W.C., 7 p.m. Mr. J. F. Sheppard, "Natural Colour Photography."

Anglo-French Society, Scala House, Tottenham Street, W., 6.15 p.m. Mr. Maurice Thiéry, "Le Théâtre d'Edmond Rostand." (Part I).

University of London, King's College, Strand, W.C., 5.30 p.m. Mr. C. A. Brayley-Hodgetts, "The Influence of English Literature on Russian Thought."

5.30 Dr. H. W. Carr, "The Principle and Method of Hegel." (Lecture III).

WEDNESDAY, MAY 17. People's League of Health, at the ROYAL SOCIETY OF ARTS, John Street, Adelphi, W.C., 8 p.m. Sir Thomas Oliver, "Physical Conditions in Relation to Health and Output."

Meteorological Society, 49, Cromwell Road, S.W., 5 p.m.

Microscopical Society, 20, Hanover Square, W., 8 p.m. Annual Pond Life Exhibition.

University of London, King's College, Strand, W.C., 5 p.m. Dr. A. Harker, "Geology." (Lecture I).

5.30 p.m. Prof. Van Bemmelen, "The Morphological Character of the Skin-Pattern in Insects and Mammals."

Bankers' Institute of, River Plate House, Finsbury Circus, 5.30 p.m. Annual General Meeting.

Automobile Engineers, Institution of, Y.M.C.A. Hall, Albion Place, Leeds, 7.30 p.m. Prof. G. E. Scholes, "Experiments on Cams and Poppet Valves."

Constructive Birth Control Society, Essex Hall, Essex Street, Strand, W.C., 8 p.m. Mr. Aylmer Maude, "The Proposal of the Doaknobbers to Murder their own Children."

Transport, Institute of, at the Institution of Civil Engineers, Great George Street, S.W., Conference, 10 a.m. 1. Sir Cyril Kirk-

patrick, "Recent Improvements in Transport Facilities in the Port of London." 2. Capt. M. H. P. Riall Sankey, "Wireless as an Aid to Transport." 3. Colonel C. H. Breesey, "The Design Construction and Maintenance of Highways in Relation to the Development of Mechanically Propelled Vehicular Traffic."

THURSDAY, MAY 18. Chadwick Public Lecture, at the ROYAL SOCIETY OF ARTS, John Street, Adelphi, W.C., 5.15 p.m. Sir Lawrence Weaver, "Rural Re-Settlement and its Relation to Public Health." (Lecture II). Royal Society, Burlington House, Piccadilly, W., 4 p.m.

Antiquaries' Society of, Burlington House, Piccadilly, 8.30 p.m.

Royal Institution, Albemarle Street, W., 3 p.m. Prof. F. Keeble, "Plant Sensitiveness." (Lecture II).

Mining and Metallurgy, Institution of, at the Geological Society, Burlington House, Piccadilly, W., 5.30 p.m.

Chemical Society, Burlington House, Piccadilly, S.W., 8 p.m. Informal Meeting.

University of London, King's College for Women, Camden Hill Road, W., 4.30 p.m. Prof. V. H. Mottram, "Metabolism of Fat and Allied Substances." (Lecture IV).

Electrical Engineers, Institution of, Savoy Place, Victoria Embankment, W.C., 6 p.m. (Kelvin Lecture) Prof. Sir Ernest Rutherford, "Electricity and Matter."

Transport, Institute of, at the Institution of Civil Engineers, Great George Street, S.W., 10 a.m. Conference continued. 1. Mr. N. Chamberlain, "Inland Water Transport a Practical Policy." 2. Sir J. E. Thornycroft, "The Future Development of Road Vehicles for Passenger and Goods Services."

FRIDAY, MAY 19. Transport, Institute of, at the ROYAL SOCIETY OF ARTS, John Street, Adelphi, W.C., 5 p.m. Mr. E. V. Russell, "The Operation of Heavy Suburban Passenger Services on a Steam Railway, with particular reference to Density of Service, Terminal and other Facilities."

At the Institution of Civil Engineers, Great George Street, S.W., 10 a.m. Conference continued. 1. Mr. D. H. Davies, "The Finance of the Modern Highway: A Problem and a Solution." 2. Prof. J. Carlier, "Foreign Railway Practice." 3. Col J. W. Pringle, "Safety in Railway Operation."

Electrical Engineers, Institution of (London Students' Section), Savoy Place, Victoria Embankment, W.C., 7 p.m. Mr. A. H. Reeves, "The Elimination of Atmospherics in Radio-Telegraphy."

Philological Society, University College, Gower Street, W.C., 8 p.m. Anniversary Meeting. Geologists' Association, University College, Gower Street, W.C., 7.30 p.m. Mr. H. Dewey, "The Sources and Transport of Non-Local Rocks in the London Area."

Royal Institution, Albemarle Street, W., 9 p.m. Prof. Sir William Bragg, "The Structure of Organic Crystals."

Anglo-French Society, Scala House, Tottenham Street, W., 6.15 p.m. M. A. Weill, "Economie Politique Internationale." (Part III).

University of London, at the London School of Economics, Houghton Street, Aldwych, W.C., 5 p.m. Dr. P. Giles, "Modern Views of Indo-European Origins." (Lecture II).

At the Birkbeck College, Bream's Buildings, Fetter Lane, E.C., 6 p.m. Dr. E. Russell, "Recent Work with regard to the Influence of Soil Conditions on Agriculture." (Lecture II).

Engineers, Junior Institution of, Caxton Hall, Westminster, S.W., 8 p.m. Mr. F. W. G. Clark, "Engineering Business in China."

SATURDAY, MAY 20. Royal Institution, Albemarle Street, W., 3 p.m. Prof. G. W. Richardson, "The Disappearing Gap between the X-Ray and Ultra Violet Spectra." (Lecture II). Municipal and County Engineers, Weymouth, South Western District Meeting.

Announcements intended for insertion in this list must be received at the SOCIETY'S Office not later than the Monday morning of the week preceding the Meeting.

Journal of the Royal Society of Arts.

VOL. LXX.

FRIDAY, MAY 19, 1922.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C. (2)

NOTICES.

NEXT WEEK.

WEDNESDAY, MAY 24th, at 8 p.m.
(Ordinary Meeting). GEORGE FLETCHER,
Department of Agriculture and Technical
Instruction for Ireland, "The Natural
Power Resources of Ireland (Coal, Peat,
Water Power)." SIR GEORGE T. BEILBY,
D.Sc., LL.D., F.R.S., Director of Fuel
Research, in the Chair.

FRIDAY, MAY 26th, at 4.30 p.m. (Indian
Section.) SIR THOMAS W. ARNOLD, C.I.E.,
D.Litt., M.A., Professor of Arabic, School
of Oriental Studies. (Sir George Birdwood
Memorial Lecture.) "Indian Painting and
Muhammadian Culture." THE RIGHT HON.
VISCOUNT PEEL, G.B.E., Secretary of State
for India, in the Chair.

TWENTY-SECOND ORDINARY MEETING.

WEDNESDAY, MAY 10th, 1922; SIR
MARTIN CONWAY, F.S.A., M.P., in the
Chair.

The following candidates were proposed
for election as Fellows of the Society: -
Hansard, John Henry, Bookham, Surrey.
Munshi, Trambakrai M., London.
Ryland, John William, J.P., F.S.A., Rowington,
Warwick.

The following candidates were balloted
for and duly elected Fellows of the Society: -
Ahuja, M. R., B.Sc., Amritsar, India.
Bhan, S. N., B.Sc., Madura District, India.
Curtis, S. Rumson, Newton Abbot.
Duxbury, George C., Margate.
Giffard, Edgar Osbert, Hove.
Gillespy, George Thomas, A.M.I.Mech.E.,
M.I.Mar.E., London.
Horne, Robert Alexander, M.I.N.A., Rangoon.
Lance, Ernest Solomon, A.M.I.E.E., Llandudno.
Maartens, William Jacobus, Bloemfontein, South
Africa.
Mehta, Jehangir Merwanji, Bombay, India.

Mehta, Manubhai Nandshankar, C.S.I., M.A.,
LL.B., Baroda, India.

Moss, Charles Samuel, Moose Jaw, Sask,
Canada.

Patel, Hormusji Dossabhoy, Bombay, India.
Rowlandson, Major Charles William St. John,
London.

Saxena, M. Amba Prasad, Rajputana, India.

Shank, John Verrall, Coorg, S. India.

Sharman, Dr. B. D., B.A., M.B., M.R.A.S.,
Calcutta, India.

Shaw, Pran Krishna, B.A., Bengal, India.

Verheyden, Dr. Cornelius, London.

Verjee, N. M. Suleman, Mombasa, Kenya
Colony.

Wood, William, London

A paper on "The Design of Repeating
Patterns for Decorative Work" was read
by MAJOR PERCY A. MACMAHON, R.A.,
LL.D., D.Sc., F.R.S.

The paper and discussion will be published
in a subsequent number of the *Journal*.

PROCEEDINGS OF THE SOCIETY.

DOMINIONS AND COLONIES SECTION.

TUESDAY, APRIL 4TH, 1922.

COLONEL THE HON. SIR JAMES ALLEN,
K.C.B., High Commissioner for New Zealand,
in the chair.

THE CHAIRMAN, in introducing the author,
Sir Thomas Robinson, said that he was one
of the old stock of Britishers who helped
materially to make the Dominions what
they were. He was a man of imagination,
and after having served his country in Queens-
land for some years, came home and served his
country as Agent-General of Queensland for
the longest period that any one had occupied
the office. He was in London when the
war broke out, and immediately offered his
services to the British Government, becoming
the Director of the Imperial Meat Supply.

For his services he had been rewarded with the Grand Cross of the British Empire, and had also been honoured by France, Italy, Belgium and other countries.

The paper read was:—

NEW ZEALAND.

By LIEUTENANT-COLONEL SIR THOMAS BILBE ROBINSON, G.B.E., K.C.M.G.

There are very few places in the world which can offer such attractions as does New Zealand, both to the man who is desirous of adventuring his fortune in the out-lying parts of the Empire, and to the traveller in search of places of interest and beauty, and it is regrettable that there are not a larger number of visitors and settlers in New Zealand, but this is doubtless due to want of knowledge of the Dominion.

The means of communication between Great Britain and New Zealand are good and there is a choice of several interesting routes.

As I was anxious to see the Panama Canal, I made the voyage on board one of the New Zealand Shipping Company's Regular Line of steamers from Southampton to Auckland, and as the vessel called at Newport News, passengers had the opportunity of visiting Washington (as we did) and also seeing something of the West Indies, as the steamer called at Kingston, Jamaica.

The journey through the canal was the more interesting as we were following the American Atlantic Fleet, which was passing through the canal to join the Pacific Fleet, and on our arrival at the other end of the Canal (at Panama) we saw the whole of the American Combined Fleets, a sight never to be forgotten, but I was glad to see at least one man-of-war there flying the Union Jack in such good and genial company.

The voyage across the Pacific from Panama to New Zealand was safely accomplished in most agreeable weather, and any possible monotony was broken by a short stay at Pitcairn Island, where we had the opportunity of making the acquaintance of some of the descendants of the mutineers of the "Bounty," a very interesting experience which one is not likely to forget.

Auckland, our first port of call in New Zealand, is situated in the North Island. The entrance to the harbour is very fine, and its beauty greatly impressed those

of us who had not visited New Zealand before.

Auckland is a fine city, with excellent shipping accommodation, but it is somewhat hilly for the pedestrians, although the undulating ground upon which the city stands adds greatly to its beauty and attractions in other respects.

The country around Auckland is exceedingly beautiful and we were at once struck with the great variety of foliage and with the more green and homelike appearance of the country when compared with Australia.

Probably the most beautiful spot in the neighbourhood is on the summit of the hills which form the high land of the Isthmus upon which Auckland stands. From the residential portions of the suburbs situate on this delightful eminence it is quite possible to view the sea on both the east and west sides of the island, but this is of course only possible at that particular point where the island is most narrow and nowhere else do the east and west coasts so nearly approach each other. The view from this high land is exceedingly beautiful, but this is only one of the many beauty spots in New Zealand, of which there are so many.

Words fail one in the endeavour to describe the many beautiful places which we saw in both the North and South Islands, all of which are worthy of a more prolonged visit than we were able to pay, but with the help of the lantern slides which follow presently some idea may be gathered of the charming and delightful character of the country. Of course all these lantern slides lose greatly by the fact that they show only the form and not the colour of the objects photographed. Some day, perhaps, when colour-photography becomes more popular and more easily practicable, it may be possible to do something more like justice to New Zealand landscapes. Those of us, however, who have actually seen the places are able, although imperfectly, to imagine the colours with which the landscape was flooded and beautified by the gorgeous sunlight and the wonderful cloud effects which make New Zealand skies so glorious.

I am not bold enough to attempt to express any balanced comparison between the several parts of the North and South Islands, the attractions and the advantages are so various and the natural wealth of the several districts so abundant. The wonderful fertility of the

soil, and the bountiful pasture available for stock, are sufficiently evidenced by the exports from the Dominion, and the extent to which New Zealand's prosperity and commerce may develop in the near future seems to depend more upon the number of successful settlers who may be attracted to her shores than upon any other limitation.

Broadly speaking, it has been determined by Nature that the North Island should be the warmer of the two. The many warm springs, steam blow-holes and evidences of active volcanic forces—often at no great distance from the surface—give a special character, and perhaps even a greater interest to this part of the Dominion, and it is fortunate that successive Governments have realised how easy it is to increase the attractions with which Nature has endowed this highly favoured Dominion.

As an instance, one remembers how Rotorua has been made more beautiful and attractive to the tourist and holiday-maker, and how much natural beauty has now been disclosed and made accessible to those who are attracted by the natural wonders which exist in that most extraordinary district.

Visitors are made welcome on the tennis courts and bowling greens, and also find the hotel accommodation all that could be desired. The hot baths and the steam blow-holes are only some of the natural curiosities which have been appropriated and improved in the lay-out and the adornment of the Pleasure and Flower Gardens, which form a striking feature of this delightful holiday resort.

The Maori Settlement at Whakarewarewa is comparatively near, and is most interesting, not only because of the present Maori Settlement there, but because of the ancient Maori stronghold, or Pa, which has, happily, been maintained in an excellent state of preservation, and is situate in such a commanding position that it may be said to be one of Nature's fortresses. The obstacles and trench formations with which the early Maoris were shrewd enough to add to the strength of the position, suggest in a most remarkable manner the form of trench which was found to be suitable for the campaign in Flanders during the recent Great War.

Travelling in both islands by railway is quite comfortable, and on the railway line there, we travelled for the first time in the type of carriage which is popularly known in New Zealand as the "bird-cage." These

carriages resemble our corridor coaches, except that the corridor is, as it were, out of doors, being only covered in by the roof, the side being composed of very open wire-work, which permits an almost unrestricted view of the country through which the train may be travelling, to those who are desirous of seeing it, and who sit outside the enclosed portion of the coach. The structure of the latter occupies about three-quarters of the width only, and thus leaves a kind of verandah upon which one may travel in comfort and enjoyment, especially during the hot weather.

The fact that the railways, both in the North and South Islands, run frequently within sight of the sea, adds greatly to the interest and enjoyment of travel, and the abundance of water, both in rivers and in lakes, throughout the Dominion, greatly increases the beauty and natural advantages of the country.

In the North Island, the large number of hot springs, and, in some cases, boiling pools, are a never-ending source of interest and attraction to travellers, and at Whakarewarewa we saw the Maori children sitting upon a piece of rock which separated a fast-running trout stream from a boiling geyser-like hole, so close to the running stream beside it, that the children were cooking in the boiling spring on one side of the rock a fish which they had only just caught with a hook from the trout stream on the other side, which seemed to be abundantly supplied with fish.

The Maoris' idea of a good site for a house and economical cooking, seemed to be over a moderately warm patch, so that in the winter time, the escaping steam would warm the interior of the house, and then to have a boiling pool as near as possible to the verandah steps, so that the wife might sit out on the verandah with her potatoes or pudding in a string bag immersed in the boiling water hole, and observe the passers-by, or chat with her neighbour while she watched the cooking of the family meal in progress by help of kindly Nature, being all the time at hand to take the string bag containing the food out of the boiling water when the cooking was completed, and the food fit for table.

We went from Rotorua to Wairaki, where the Rest-house accommodation was again most comfortable, and a morning walk up the adjacent valley, among the hot springs and geysers, was one of the

most interesting that we were able to make. The periodicity of these hot water geysers is so well known that it is possible to visit all by the help of a time-table, and be there at the moment when they are in the greatest activity. They vary even where two or more hot springs discharge into the same cavity of the rock, and the guides are able to tell you at what time each particular geyser will next display its greatest force and beauty.

It is impossible to conclude what one desires to say about this particular neighbourhood without reference to the wonderful steam blow-hole, which it is desirable to see at night, when the immense masses of vapour can be illuminated with coloured lights, and so rendered extremely beautiful by this and other means. In order to display the enormous force of this blast of steam, it is customary for visitors to throw in empty kerosene tins and watch them being projected into the air and falling again to the ground, the noise they make in falling mingling with the noise of the steam escaping through the rocks.

We were informed that the pressure of the steam at the point of its escape from the rock exceeds 350 lbs. to the square inch, and it is common knowledge that this escape has been in operation for the last fifty years without a moment's cessation. Up to the present, no attempt has apparently been made to harness this immense force, or turn it to some beneficial use, although it appeared to us from the conformation of the rocks through which it issues, that this might be accomplished with comparative ease, and at a very moderate cost. It is true that this escaping steam is at some distance from any present settlement, but it does seem a great pity that no steps have yet been taken to utilise such a bountiful and apparently inexhaustible source of power for commercial or beneficial purposes.

Fortunately, on the outward voyage, one of our fellow passengers, who had made the journey down the Wanganui River, had shown us some photographs which indicated, but all too inadequately, the natural beauties of that wonderful river and the country through which it passes. In order to see it for ourselves, we went up by rail to Taumarunui, and there joined a small launch which was of sufficiently shallow draught to enable her, under ordinary circumstances, to get down through the shallows and over the rocks with which

the upper portion of the river is beset. At the time we were there, the rainfall had been somewhat less than usual, and, in consequence, the water in the river was low. The launch which usually made the passage had evidently been stuck down the river on some of the crossings, and so we started from Taumarunui in a smaller craft, but a few hours later came upon the larger vessel, which it had been found impossible to bring up any higher that day. We trans-shipped into the larger launch, and the change was very welcome, for we had been joined by a few other passengers, including a number of Maoris, and the more roomy accommodation of the larger launch was much appreciated. It also gave us opportunity to move about and make the acquaintance of some of our fellow passengers, who, knowing the district, were good enough to tell us something of the country through which the river flowed.

The boats were steered and poled by Maoris with great skill. In some places the water was so shallow that the boat could only be got over the rocks and rapids if the passengers disembarked and made the stage on foot, re-joining the launch again at some distance down the river where the deeper water permitted its navigation with passengers on board.

We stopped at a number of places on the way down, occasionally disembarking and picking up passengers and mails. At one point in particular, we were very much amused by the farewell which was being given to some of the Maori passengers by their friends and relatives, although the passengers who joined us were only expected to be away for a few days.

By sundown we had reached the house-boat moored about one third of the way down, where we spent the night most comfortably, and started again immediately after breakfast at 6 a.m. next morning.

We had intended to go right down to Wanganui, but a telegram intimating that Mr. Massey, the Prime Minister, was anxious to see me, reached us, and we, therefore, determined that, as the most interesting parts of the river had been passed, we would disembark at Pipiriki, where we arrived at noon on the second day.

We left Pipiriki by motor car and went over some very beautiful pasture land and wooded country to the railway, and so got into Wellington a few hours later.

Before leaving the North Island, we, of course, saw some of the other rivers, as well as some of the larger lakes, and we are never likely to forget the wonderful fishing which we enjoyed at Lake Taupo and on the Waikato River. The newly-caught fish cooked upon the beach on the fire and on the hot stones, made the water picnics most enjoyable, and the fishing far exceeded anything which we had thought possible. The sport was wonderfully fine, and the fish were game, of good size, and were most delicious eating. In fact, we came to the conclusion that for the trout fishing alone, it was well worth making the voyage to New Zealand.

In one of the rivers where we were fishing we were told the fish were so plentiful that at one season of the year it was no unusual thing to see the wild pigs catching them and eating them; they are so thick in places that the pigs, by wading into the pools where the fish are accustomed to congregate, manage to catch them in their mouths quite easily.

Speaking of fish reminds me that near an old Maori redoubt, which we visited in company with Judge Aitchison, with whom we happened to be fellow-travellers, we saw a lake into which an underground river discharges and from which, once a year, a very rare species of blind fish issues, but for a short time only, for after a few hours they return from the lake to the underground river from whence they came. During that short period, however, the Maoris, who know the day on which the fish invariably come out, catch them in great numbers and dry them for use as winter food.

It was in the North Island that we first saw the Maoris at home and among their natural surroundings. The difference between the Maori and the Australian Aboriginal is very striking. Physically the Maoris are greatly superior to most of the Australian Aborigines and in their habits, their mechanical attainments, their intelligence and their nature they are very different from the natives of Australia. In nearly every instance we found them to be naturally intelligent, polite and friendly folk. They have great self-respect and in many ways they are accustomed to meet their fellow white-Colonists on equal terms. They are a most interesting race and are of a most hospitable disposition. Their pride of descent is great and their knowledge of their

ancestors is most accurate. The ownership of the land is easily ascertained and can be accurately settled because of the knowledge which the Maori possesses of his progenitors and their possessions, the land being held in common by the family or tribe settled in the respective districts. By a wise provision of the law the sale of Maori owned land must be made through Government channels and the Maoris greatly appreciate the fairness with which the sales of land have from time to time been negotiated by the Government on their behalf.

The traditions of the Maoris go back to very remote periods and in the distant past their settlement is said to have resulted from the arrival of large canoes laden with their ancestors, who came from other islands under the direction and guidance of bold leaders and great medicine men.

Maori folk-lore is extremely interesting. The mentality of the Maoris is distinctly poetical, and their knowledge of their past history is handed down from generation to generation with such care and faithfulness that in many cases it has been possible to obtain from the tribal traditions clear and fairly accurate history of their past.

The natural phenomena among which they live seems to have influenced the minds and impressed the imagination of the Maoris in the most wonderful manner. There are innumerable evidences of their poetical imagination and the following is a typical example:—

“Mount Kakepuka is situated in the
“Valley of Waipa. It has fern covered
“slopes and culminates in a crater-like
“summit 1,400 feet high. Kakepuka is a
“perfect type of an extinct volcano.

“A few miles east of Kakepuka stands
“Kawa, a rounded hill with a crater on
“its southern side and its slopes cut into
“the terraces of an ancient Pa. In the dim
“long ago, says the Maori tradition,
“these mountains were sentient beings
“with human-like passions. Kawa was
“a female mountain, Kakepuka was a
“male and in those days there stood
“near Kakepuka and Kawa another
“hill called Karewa, who also was a male
“mountain. Kakepuka came originally
“from the south searching for his father
“and was strolling about the Waipa
“Valley in a mountainous sort of way
“when he espied Kawa, the daughter
“of Mount Pirongia and Taupiri and fell

"in love with her, so he remained there
 "by the side of Kawa Hill. Karewa
 "and Kakepuka both made fiery and
 "fierce love to Miss Kawa, quite after the
 "primitive fashion of volcanoes, and being
 "jealous of each other quarrelled. The
 "result was a titanic fight, a battle of
 "mountains. Karewa was badly beaten
 "by his big rival and had to trek. He
 "took up his rocky traps in the night and
 "marched westward by way of Kawhia,
 "striding into the deep ocean, and there
 "he let down his moorings and stayed
 "where the dawn found him, and so out
 "in the Tasman sea sits the lone Isle of
 "Karewa (which the Pakeha calls Gunnet
 "Island), while back in the valley of
 "the Waipa, Mount Kakepuka keeps a
 "majestic watch over Kawa, his gently
 "rounded, fern clad spouse. Kakepuka is
 "the weather glass of the countryside.
 "When he puts on his white cloud cap
 "and his old crater mouth is hidden in
 "fog and mist, it is better to strap your
 "rain-coat to your saddle bow. But
 "when on Kawa's ferny head the soft wet
 "mists come down, and when the long
 "wispy streamers of damp smoke-like
 "vapour cling round her terraced slopes
 "and are wafted over the plains on the
 "gentle seaward blowing breezes, that
 "is Kawa sending her tearful Miki of
 "love and sorrow to her far-off lost lover
 "Karewa."

That the Maori is fit to take his place
 beside the white man in the defence of his
 country, was surely demonstrated by
 the heroic manner in which he upheld the
 reputation of his race alongside the other
 New Zealand soldiers who fought in the
 Great War. There is no doubt that the
 race has, in the past as well as in the present,
 produced great warriors and sturdy men
 of war.

Even yet there are traces of the fortifica-
 tions and defensive works upon the battle-
 fields on which great Maori tribal wars were
 fought in by-gone days, and around these
 linger traditions which are happily being
 preserved, and which will for ever make
 the places with which they are associated
 of interest to students of New Zealand
 history. But I must not any longer linger
 over this and other subjects and places
 that make the North Island so attractive.
 nor is there time to do justice to the
 many interests, political and commercial,
 which are centred in and about Wellington

and the other ports and places which we
 visited.

The crossing from the North to the South
 Island is by ferry steamer of magnificent
 size and equipment, and is comfortable,
 even in bad weather.

One of the two vessels engaged in this
 service leaves Wellington every night,
 and reaches Lyttelton in the South Island
 early the next morning. The railway
 journey from thence to Christchurch
 (through a somewhat remarkable tunnel)
 is accomplished in a very short time.

Christchurch is a very charming and well-
 planned city. In some respects it has
 advantages over Wellington, and has
 certainly a charm and beauty entirely its
 own. Through the centre of the town
 runs the river; lined with green, grassy
 banks, and flowering shrubs and trees, this
 is a never-failing source of interest, and
 adds greatly to the beauty of the city.

As in Wellington, there is a good tram
 service, and the surface of the surrounding
 country, as well as the site of the city, is,
 in contrast to Wellington and Auckland,
 wonderfully flat and even, thus favouring
 easy locomotion.

In one important respect, there is a strik-
 ing difference between the Southern Austra-
 lian States and New Zealand; for while
 in Victoria nearly the whole of the shipping
 and commerce is centred in Melbourne,
 and in New South Wales so much of the
 shipping and commercial life is centred in
 Sydney, no such concentration exists in
 New Zealand. Presumably this is because of
 the numerous ports along her coasts, at
 each of which the exports from the surround-
 ing districts make it worth while for over-
 seas vessels to call, with the result that
 there are a number of ports in both the
 North and South Islands regularly visited
 by overseas steamers, each port enjoying
 and developing its own overseas trade.
 In consequence, there are quite a number of
 large towns and cities already existing, and
 in course of development, and this so dis-
 tributes the centres of commerce and popu-
 lation throughout New Zealand, that the
 congested and overgrown capitals of some of
 the Australian States have, happily, no
 parallel in New Zealand. This is, of course,
 greatly to the advantage of the latter
 Dominion, and results not only in a better
 distribution of the population, but also in
 a happier combination of town and country
 settlement than has yet been attained in

most of the Australian States. With the development of a number of important ports and cities such as exist in both Islands of New Zealand, closer settlement goes hand in hand. These several cities and ports give a near-at-hand market to producers, and foster a local patriotism and spirit of friendly emulation which must be of great advantage in the settlement of the Dominion.

The interest taken by Sir Joseph Kinsey in Antarctic discovery and the assistance which he rendered to those lion-hearted sons of the Empire is well known, and while at Christchurch we had more than one opportunity to hear from him details of the voyage of the S.Y. "Discovery" and the mishaps and adventures of Scott and his devoted fellow-voyagers. Sir J. Kinsey was good enough to show us his treasured relics of the expedition and we are indebted to him for some of the excellent lantern slides which we shall see presently. His collection of New Zealand native green stone ornaments and tools is of course very fine, but it was surprising to find in so unexpected a place such exquisite and interesting miniatures together with many other beautiful things including a varied and valuable collection of Japanese swords.

Our friends were so good to us there that I find it a pleasure to linger over a gossip about the pleasant recollection of our visits to Christchurch, as it was to postpone, as we did, more than once, our departure from that city because we liked the place and the people so much.

From Christchurch we travelled south by railway through some very beautiful scenery (especially in the neighbourhood of Port Chalmers) to the southern point of the South Island, and in Invercargill we were taken to see a well-known landmark, which was none other than an ordinary cast iron lamp post, such as one sees in many suburban streets in England. The interest attaching to this particular light-bearing standard arises from the fact that it is the nearest lamp-post to the south pole.

From Invercargill we went by rail to Kingstown and from thence by lake steamer to Queenstown. The latter half of the journey was particularly interesting, because of the majestic scenery by which the lake waters are surrounded, and to our great delight we were able, while upon this passage, to see the mountains known as the Remarkables covered with snow. The snow

was an unexpected addition to the beauty of the landscape and had, as a matter of fact, fallen only the day before.

Queenstown is a comparatively small township, and although we were told it has less than a thousand inhabitants, it already possesses some very beautiful recreation gardens and terraced walks laid out upon a promontory jutting into the lake, just opposite to the landing stage. Our stay there was all too short, for there was some very interesting mountain climbing possible, which began almost at the hotel door.

Visitors to Queenstown should certainly take a drive to Skippers. The journey up the Range and through the Gorge to the site of the sluicing operations is exceedingly interesting and beautiful. On the one hand the road winds along the face of precipitous cliffs which rise abruptly to great heights from the narrow shelf along which traffic is possible, while on the other hand there is a sheer fall of, in some cases, hundreds of feet into the ravine below through which a raging torrent can be both seen and heard finding its way to the lower country.

The contour of the rocky formations assumes forms which are both majestic and grotesque. At one place we were shown an immense out-crop of rock on the mountain side which was called "Edinburgh Castle." At another place the outline of a far-off hill resembled the profile of Queen Victoria. There were other places and perilous passes whose weird names I shall avoid repeating for fear they should discourage travellers from making a most interesting journey which they might ever afterwards regret they had missed.

I do not mind confessing that, when the journey was over and we were safely back again, we felt that a watchful Providence had been good to us that day, for the very small margin of safety between the outer wheel track and the edge of the rock was surprisingly small at places, and I wonder to this day what happens when two vehicles meet on that long and narrow shelf, where there seems, except at one place (a little settlement) no room whatever for one vehicle to pass another. As there is no provision for enabling one vehicle to pass another on the track I am still wondering whether it is worked on the lines of a single track railway by a system of driver's staff, or some wonderful method of signalling which so operates as to

prevent more than one vehicle travelling on the road at any one time.

Of course the track is impossible for motor cars and only pedestrians and horse vehicles are allowed to use it.

At the time we were there, no gold to speak of was being recovered, but we were fortunate enough to secure a specimen of the alluvial gold which is sometimes found in this locality and which we have brought home with us as a treasured souvenir of a most adventurous and delightful day, but only one of the many which we spent in New Zealand.

We climbed one of the big hills there, called "Ben Lomond," until we got well into the snow line, and then, as the snow began to fall again, we thought it prudent to abandon our intention of climbing to the summit, but we did so with great reluctance, for the view from the hill across the lake, both in the direction of Paradise (which is situate at the head of the lake) and toward the Remarkables on the other hand, was worth climbing a long distance to see.

From Queenstown we went by motor car across country to Mount Cook. Our adventurous journeys across the Crown Range and through Lindis Pass, were full of interest and delightful, as well as, sometimes, somewhat disconcerting experiences. A broken down motor car on a mountain range, calls for mechanical skill which is not always available, and when our difficulties which arose from that cause were (after some hours' delay) happily overcome, we were exceedingly glad to partake of the kindly hospitality of a road mending party, the members of which turned out of their bunks long after dark to boil water and make us tea, while they regaled us with welcome chunks of bread and jam. It gives me great pleasure to express, on this side of the globe, our appreciation of the great kindness which we experienced at the hands of this road party, and the gratitude which we felt for their kindly hospitality after a long mountainous journey, upon which we had had plenty of hard work, a long trip in the dark without lights, and with nothing to eat for many hours.

We waited at Lindis Pass until another motor car came to our rescue. Here we were in the deer country and it surprised me to find that in some cases settlers found it necessary to erect fences eight to ten feet high to prevent the deer, of which there

were a large number in that locality, from jumping over into the cultivated areas and eating up or destroying the crops. We had venison and rabbit for every meal, and fared sumptuously there, as we did also everywhere else in New Zealand. There had been no need for rationing there, for they have had fruit and food in abundance always.

From Lindis Pass we continued our journey across country, but, happily, upon this occasion in a motor car not quite so liable to break down as the one in which we had made the first part of the journey. We travelled over excellent country and good pasture land (as yet very sparsely settled) for the greater part of the way. The roads were exceedingly good and we made excellent running until we arrived at the Resthouse at Pukaki, the last stage before reaching Mount Cook. Our progress at this point was arrested by a telephone message which had come through from Mount Cook, stating that there had been heavy rain along the road, and that Wood Creek was running in flood in consequence; that a motor car, which had attempted to get through that morning had got into deep water, and had, in consequence, been abandoned in the Creek, which, for the time being, was impassable. We waited for a few hours, and then, having word that the Creek was reported to be falling, we made up our minds to attempt the journey, although it was now so late in the afternoon that no inconsiderable portion of the journey would have to be made in the dark. We reached Wood Creek without mishap, and ultimately managed to get across, although we had a bad five minutes when our motor stopped in the Creek only about forty or fifty yards away from the abandoned car, which was almost submerged. Our driver promptly jumped out into the water and managed to start the engine again, and with the help of the Road Superintendent, who was good enough to accompany us, we managed to zig-zag across on to higher ground; the water was never much above the floor of the car, and we ultimately got safely across. Being the first passengers to make the crossing subsequent to the rising of the Creek, our arrival was anxiously looked for at Mount Cook by the people who were waiting for the Creek waters to subside, and when our head-lights were sighted, they waved us a lantern welcome, and by the time we reached the Hermitage

they had made a most abundant dinner ready for us, much to our satisfaction and enjoyment.

The Hermitage Resthouse, maintained by the Government, is at the foot of the Mount Cook Gorge. It is exceedingly comfortable and well appointed. Visitors are not, as yet, so numerous as one would expect them to be, but the organisation and arrangements generally for accommodation, climbing and guidance of visitors, are all that could be wished. The kindly interest and the courtesy shown to us and other visitors by Mr. Peter Graham, the chief guide, added much to the pleasure of the visit to Mount Cook.

The view from the Hermitage of the surrounding mountains is indeed very beautiful and at sunset the gorgeous colouring of the snow-capped peak of Mount Cook is most brilliant and beautiful beyond description.

We were fortunate while in New Zealand to make the acquaintance of two gentlemen who had climbed to the summit of Mount Cook, and as both have published a full and interesting account of their experiences we were fairly conversant with the details of their climb and journey to the top, but our interest was greatly increased by the further details which were elicited in conversation with the climbers, and in particular with Mr. Turner, the only man who has made the ascent alone and reached the summit without guide or assistance. We are inclined to think that the eventful journey which he made alone after several years of preparation and waiting for a favourable opportunity, had been prompted by some question which arose as to which member of the party who made the ascent previously should be conceded the greatest credit for the mountaineering skill exhibited on that occasion; but after the solitary climb of the gentleman named there could, of course, be no question as to his mountaineering skill and indomitable courage, no matter to what extent the same could be claimed for the others in whose company he had made the earlier climb.

Although none of our party attempted such an adventurous trip as the ascent of Mount Cook, we were all keen to climb some portion of the mountains by which we were surrounded, and as we were favoured with exceptionally fine weather we were able to make several ascents, but of course of only minor importance.

The Stocking Glacier being within comparatively easy distance of Hermitage Resthouse, we began there, and although the climb was exceedingly difficult and tiring in places we ultimately reached the glacier, where we saw the most wonderful colours in the snow cavities and caves. The extraordinary effect of the passage of the ice through and over the rocks gave one a very vivid idea of the extent to which the movement of a glacier over the surface of the country may alter the features and contour of the valleys through which it passes on its way to the sea.

In years to come the Alpine fastnesses of New Zealand will surely attract many climbers, and I venture to suggest to the Alpine Club that if the mountains in New Zealand were better known they would attract climbers from England in spite of their distance from this country.

From Mount Cook we travelled eastward towards the coast, spending a few delightful days with some friends upon both sheep and cattle stations. We should have liked to prolong our stay so that we might have seen more of the Dominion, but we could not spare any more time, as it was necessary for us to go on to Australia without further delay.

Although I have mentioned some of the fish which may be found in abundance in the lakes and rivers, I have said nothing about the sea-fish, which abound on the coast. Among the lantern slides we shall find a picture of "Pelorus Jack," the extraordinary fish which used to pilot every ship which passed through Cook Strait from Wellington to Christchurch for years, but is now apparently dead, as he has not been seen for some considerable time.

Then there is the extraordinary Frost Fish, no specimen of which has ever yet been caught either by line or net, and which can only be found if sought for on the beach after a frosty night. It is an excellent table fish and is regarded as a great delicacy.

New Zealand birds deserve a lecture all to themselves. There are some very interesting and very beautiful specimens, but I will only mention two. First the delightful little fantail, which flits about one's head and accompanies wanderers in the hush and in the gardens in the most extraordinarily friendly and confiding manner. I have never succeeded in getting one to perch upon my finger, but have frequently

induced them to perch on a short stick held in my hand for that purpose. The birds are of course wild and are very graceful and beautiful in appearance.

The other bird to which I refer is the kea and is of quite a different character. He has in some way discovered that the kidney of a sheep is agreeable to his palate and in his vicious attempts to secure the desired delicacy he kills the unfortunate sheep by tearing open its back, and curiously enough just at the identical spot at which the kidney can be most easily abstracted from its ill-fated owner.

There is so much that might be said about the wonderful strides which have been made in the dairying industry and the success with which butter and cheese are produced and graded, exported and marketed. In this respect New Zealand is said to be still in advance of Australia.

That New Zealand contributes an important proportion of the mutton and lamb upon which British consumers depend for their food is, of course, well known, but time forbids my dealing with this subject upon the present occasion.

There is an abundance of fruit in New Zealand. In some of the gardens at Christchurch we saw as much fruit which had fallen off the trees and was lying on the ground as would have stocked Covent Garden Market, and there is no doubt that in the near future New Zealand will successfully compete with Australia for a share of the British markets, so far as apples and pears are concerned.

If time had permitted, I should like to have said something about the gum industry, the growth and cultivation of flax, and the steps which have been taken to maintain and increase the growth of timber, and in this connection I would like to mention that on one of our journeys we passed through Crown Lands, of which 25,000 acres had been closely planted with young pine trees. This had all been done by prisoners' labour, a very excellent way of employing prisoners and one which is said to have a beneficial effect upon their subsequent conduct. It is impossible however to do justice to any of these subjects in the time at my disposal.

In conclusion let me say that to those who have leisure to visit the more distant and beautiful parts of the Empire, New Zealand offers many attractions and a hearty welcome, while to those in search of greater opportunities and brighter surroundings than the

Old Country now affords to some of her people, New Zealand offers the promise of success and prosperity which seems to follow so certainly upon the industry and effort of those who are privileged to live within her borders. We Australians may perhaps be insufficiently informed as to the attractions from which we are separated by a short sea voyage and are consequently missing opportunities of a delightful change in neglecting to visit New Zealand more frequently than we do, but the safety, progress, and prosperity of the Dominion and the Commonwealth are so inseparably connected that as time passes the bonds and associations by which we are united must inevitably be increased and strengthened to our mutual advantage and the good of the Empire.

DISCUSSION.

THE CHAIRMAN (Colonel the Hon. Sir James Allen), observed that New Zealand was a country of great production and he should like to have descanted upon it at some length if time had permitted. He would have to content himself by saying that it was a land of beauty and imagination, a place for tourists, a place for those who were seeking their health, not only on account of the climate but because of the natural hot waters and springs, and a place of sport. These aspects in New Zealand were not sufficiently known to the people of Great Britain. There was, he believed, no more beautiful country in the world, and no country that boasted such a variety of scenery of all kinds in so small a place as New Zealand. He thought they could get the best trout fishing in the world there; trout up to 37 lbs. could be caught with rod and line. Salmon were now running in most of the rivers, while in the seas around the country a different type of sport could be got in catching kingfish, which ran up to 80 lbs., and were also caught with rod and line. They could imagine what sort of sport an 80 lb. fish would give an angler on the rod and line. As to the health resorts, if they wanted to go to a place where they were almost certain to recover from diverse complaints—he would not say all complaints—they should go to New Zealand and sample the hot springs and the hot baths and the climate and the sun and the atmosphere. Then, if they wanted to give full play to their imagination, they could enjoy the mysteries of the stories of the Maoris and of ancient times, and though New Zealand was prosaic in regard to its products of mutton and beef and lamb and butter and cheese and wool there was another side to the lives of its population, and that was one it was as well to cultivate. The native of New Zealand had been referred to by Sir Thomas Robinson,

and all he said on the subject was true. There were no finer natives in the world than the Maoris and the Polynesians. When the war broke out the Maoris were the first to come forward. Out of a comparatively small population, 3,227 joined the fighting forces, and those who came in contact with them during the war agreed that they were as good soldiers as could be found anywhere. They volunteered in the early stages, and their volunteering was always free and full. When the Military Service Act was introduced he had a special clause inserted to authorise him as Minister of Defence not to apply the Military Service to the Maoris unless he deemed it necessary. The Compulsory Act was not applied to the Maoris until towards the end. There was one tribe who thought they had a grievance against the whites, a very old one. He was obliged to apply the Act to that tribe, and one of the men who came to camp went back to the rest and said "I have my experience of camp and think you should all come in." The whites lived happily with the natives, who were given equal opportunities.

THE HON. A. M. MYERS, Member of the New Zealand National Ministry, 1915-1919, remarked that no one who had visited New Zealand as a tourist had ever been disappointed. He was asked to say a few words from the probable settler's point of view. When representatives of all the Overseas Dominions were urging that their own particular state was the most suitable for emigrants, no greater testimonial could have been given to New Zealand than the fact that they had from Sir Thomas, a former representative of one of the sister states, Tasmania, such a splendid eulogy of New Zealand. In New Zealand they had practically no unemployment. Financially, like other countries, they had been passing through difficult times, but they had a population which was most virile, very industrious, and living in surroundings in every way conducive to turning out millions' worth of products attractive to customers on this side of the world. He did not for a moment hesitate to suggest to anyone who was desirous of leaving the Mother Country that he should direct his steps to New Zealand. Her trade, principally with the Mother Country, per head of population was larger than that of any other country in the world. The laws were very liberal; they had enjoyed the full franchise for over a quarter of a century; free access to the land was given to people of comparatively small means; and although they had had a land boom, owing to the high price products realised during recent years, now there was no doubt that land would be obtainable at a reasonable price in the future. The price of their staple products was improving. There had been a set back, but there was no doubt they had turned the corner, and the

future of New Zealand was as bright as it could possibly be. Any emigrant, if prepared to be industrious and frugal, was assured of success.

SIR JAMES MILLS, K.C.M.G., Chairman of the Union Steamship Company of New Zealand, in proposing a vote of thanks to the author said he hoped that Sir Thomas Robinson's excellent address would find its way to many thousands of readers, and so stimulate their interest in the dominion to which many of those present belonged and were proud to belong.

MR. BYRON BRENNAN, C.M.G., in seconding the motion said they had been reading lately about the question what they should do with their sons, and the answer to that question had been given that evening.

The motion was carried unanimously and acknowledged by Sir Thomas Robinson.

NOTES ON BOOKS.

THE PETROLEUM INDUSTRY: A BRIEF SURVEY OF THE TECHNOLOGY, BASED UPON A COURSE OF LECTURES GIVEN BY MEMBERS OF THE INSTITUTION OF PETROLEUM TECHNOLOGISTS. Editor, A. E. Dunstan. London: The Institution of Petroleum Technologists, 5, John Street, Adelphi. 1922. 14s. 6d. net.

Here we have an unusually satisfactory example of that difficult literary operation of so ordering a large number of contributions as to produce a well fitted and sequent whole. Thus the reader of this book has before him a clear, readable, exact and well illustrated story of petroleum, from the earliest mentions to that climax in use, the modern Diesel engine for marine purposes.

The numerous illustrations of this volume of 346 large octavo pages, and the notable thoroughness with which the main-line aspect is considered, are the chief factors which give it the exceptional quality of being equally useful to the general reader and to the expert technologist.

The constructive materials of the book are Sir Frederick Black's introductory lecture; Sir Boverton Redwood's Royal Institution lecture on the Romance of Petroleum; Mr. Cunningham-Craig on Wild-Catting; Mr. George Howell on Prospecting; Mr. H. May on Oil-field Practice; Mr. H. Barringer on Transport, Storage and Distribution; Mr. A. E. Dunstan (Editor) on Refining; Mr. F. B. Thole on The Chemical Nature of Petroleum; Mr. W. R. Ormandy and Mr. J. S. S. Brame on The Uses of Petroleum; Mr. J. Kewley on Nomenclature; Mr. A. W. Eartlake on Statistics, and Mr. W. H. Dalton on Text Books.

On p. 9, the reader may see a photographic illustration of a pitch spring at Zante, as

mentioned by Herodotus, who wrote about 2,400 years ago, and the picture shows the lifting of the viscous pitch from beneath the water by a tree branch, just as the Father of History describes the operation. It is, however, worthy of passing note that Herodotus refers to the matter as bearing on a Phœnician story he had heard, about a method of gold-getting by a surface smeared with viscous petroleum, a story so remarkable that Herodotus could not at first credit it: but a study of the mode of dipping out pitch at Zante led him to regard the story as probably correct. (Herodotus, cap. IV., sect. 195, p. 338 of George Long's text, London, 1851.) Herodotus incidentally touches on the tanking, and the storage in jars of the pitch at Zante. His Phœnician story as to gold getting may not seem altogether incredible to a modern laboratory worker who has studied certain aspects of surface tension and adhesion as affected by water, and an application of the notion to the separation of minute grains of heavy metals, which, like platinum, resist amalgamation, may be worth attention.

The old Burma oil well (Fig. 2, p. 23), the Assam oil field (Fig. 4), and the remarkable picture of a Mesopotamian refinery on p. 32, which latter suggests a desert studded with a few gipsy tents from which smoke issues, all savour of the slow-changing East, but when we read of Wild-Catting in the West (p. 36), the note changes. The wild-cat is the first well of a new oil field, and if the field is good, the first spit of the wild cat is a torrential push, such as is vividly described on p. 37.

To minimise failure in wild-catting, there should be a wide combination of qualities in the prospector, who should be able to trace the various porous strata whether loose or compact; also, he must be able to judge as to the outlines and formation of the anticlines or subterranean dome-like receptacles in the impervious strata. In these anticlines which are often extremely irregular in formation, the natural gas collects at the higher levels, the oil in the medial levels and water below. As the pressure of the gas may be many hundred pounds to the square inch (p. 56), one can easily realise the active burst-forth on release.

Owing, however, to the highly complex conditions which are incidental to the subterranean domes—if indeed the term dome can be applied to such irregular inverted cisterns as are figured on pages 64 and 65—the surprisingly large areas which may be linked together by porous strata acting more or less as natural pipe lines, and also the many other matters set forth in Mr. Howell's section of the work, anything like uniform success in prospecting must appear almost impossible; yet it appears that in prospecting with ripe knowledge and careful study as an equipment, instead of mere or bare hope, as too often in former times, there may

be, if not certainty, yet a very firm belief that the first or experimental well will yield oil.

So remarkable and interesting are the conditions affecting prospecting that the section on this subject may be studied as casting a side light on the problems of life, as in the case of a good novel or the study of chess.

"The Winning of Oil" is the title of the section which treats of engineering and other details of the operations from the driving of the well to the securing or first tanking of the crude product, and as this work is often carried out in districts void of fuel and water, an element of provision comparable to modern army commissariat steps in, even to the arrangement of games for the workers. The technical details of driving, jointing, percussion, drilling and "fishing" will open out many lines of thought to one with mechanical instincts. Under "Transport, Storage and Distribution," we read of tank ships and the organisation which brings "kerosine" to our doors, although at no stage has it been packed for transit.

The chapter on nomenclature, with glossary of business and colloquial terms as they have settled down by usage and tacit consent, is admirable because real *Gas*, for example, is not defined by reference to any law of thermodynamics, but we are curtly told that in the United States it is a short form for gasoline. It was, we think, Mr. Robert Barr who laid it down that a Briton finds American to be the easiest of all foreign languages as far as a superficial knowledge is concerned, but the most difficult of all in relation to a thorough scholarship.

The uses of petroleum are so diverse that the well illustrated sections on this subject offer the difficulty of choosing something for mention, but if the reader opens the book at pages 262 and 263, he will see how cows are milked by petrol drive and electric intermediary, and also two other illustrations of farm operations, but the consummation of the work centres on the Diesel marine engine, as figured on p. 309, and the illustrations of semi-Diesel principle shown on p. 304. Apart from the question of using the so-called "colloidal fuel" (a *quasi*-emulsion of petroleum and coal) in such engines, we are reminded on p. 69 that Canada alone gives reserves in coals suitable for distillation into liquid fuels of over 1,190,000,000,000 tons; while on pp. 5 and 6 the problem of growing liquid fuel in the form of alcohol is briefly considered.

MEETINGS OF THE SOCIETY.

ORDINARY MEETINGS.

Wednesdays:—

MAY 24 (at 8 p.m.)—GEORGE FLETCHER, Department of Agriculture and Technical Instruction for Ireland, "The Natural Power Resources of Ireland." SIR GEORGE T.

BEILBY, D.Sc., LL.D., F.R.S., Director of Fuel Research, in the chair.

MAY 31 (at 3 p.m.)—**LAWRENCE HAWARD, M.A.**, Curator of the City Art Gallery, Manchester, "The Manchester Art Gallery and the Problem of Provincial Collections." **SIR CHARLES J. HOLMES, D.Litt., F.S.A.**, Director of the National Gallery, in the chair.

INDIAN SECTION.

Friday afternoons at 4.30 o'clock:—

MAY 26.—**SIR THOMAS W. ARNOLD, C.I.E., D.Litt., M.A.**, Professor of Arabic, School of Oriental Studies. (Sir George Birdwood Memorial Lecture.) "Indian Painting and Muhammadan Culture." **THE RIGHT HON. VISCOUNT PEEL, G.B.E.**, Secretary of State for India, in the chair.

JUNE 23.—**F. W. Woods, C.I.E.**, late Chief Engineer, Irrigation Department, Punjab, "Irrigation Enterprise in India." **LORD LAMINGTON, G.C.M.G., G.C.I.E.**, Governor of Bombay, 1903-7, in the chair.

Date to be hereafter announced:—

J. T. MARTEN, I.C.S., M.A., "The Indian Census."

DOMINIONS AND COLONIES SECTION.

FRIDAY, JUNE 9, at 4.30 p.m.—**MAJOR SIR HUMPHREY LEGGETT, D.S.O., R.E.**, "Tanganyika Territory (formerly German East Africa)."

MEETINGS OF OTHER SOCIETIES FOR THE ENSUING WEEK.

MONDAY, MAY 22. Geographical Society, 135, New Bond Street, W., 8.30 p.m. Mr. H. Lee Shuttleworth, "The Border Countries of the Punjab Himalaya."

University of London, King's College, Strand, W.C., 5 p.m. Prof. G. B. Bray, "The Place of Sacred Gifts in Hebrew Practice and Thought." (Lecture III.), 5.30 p.m. Prof. F. H. Edgeworth, "The Development of the Head Muscles of Vertebrates." (Lecture I.)

TUESDAY, MAY 23. University of London, King's College, Strand, W.C., 5.30 p.m. Rev. R. G. Laffan, "The Serbo-Croat-Slovene Kingdom after the War." 5.30 p.m. Dr. H. W. Carr, "The Principle and Method of Hegel." (Lecture IV.). 5.30 p.m. Prof. F. H. Edgeworth, "The Development of the Head Muscles of Vertebrates." (Lecture II.)

Photographic Society, 35, Russell Square, W.C., 7 p.m. Technical Meeting.

Anthropological Institute, 50, Great Russell Street, W.C., 8.15 p.m. Dr. B. Malenowski, "Theory and Practice of Witchcraft in Eastern New Guinea."

Colonial Institute, Hotel Victoria, Northumberland Avenue, W.C., 4 p.m. Mr. Cecil Clementi, "Colonisation in British Guiana."

Zoological Society, Regent's Park, N.W., 5.30 p.m.

Anglo-French Society, Scala House, Tottenham Street, W., 6.15 p.m. M. Maurice Thiéry "Le Théâtre d'Edmond Rostand." (Part II.)

Royal Institution, Albemarle Street, W., 3 p.m. Prof. W. Bulloch, "Tyndall's Biological Researches and the Foundations of Bacteriology." (Lecture II.)

WEDNESDAY, MAY 24. People's League of Health, at the ROYAL SOCIETY OF ARTS, John Street, Adelphi, W.C., 6 p.m. Dr. Leonard Hill, "Personal Hygiene and the Importance of Food and Sufficient Sleep; Standards of Living and Family Welfare."

University of London, King's College, Strand, W.C., 4 p.m. Dr. A. Harker, "Geology." (Lecture II.) 5.30 p.m. Prof. F. H. Edgeworth, "The Development of the Head Muscles of Vertebrates." (Lecture III.)

British Academy, at the Royal Society, Burlington House, Piccadilly, W., 5 p.m. Mr. E. Hutton, "Some Aspects of the Genius of Boccaccio."

Linnean Society, Burlington House, Piccadilly, W., 3 p.m. Anniversary Meeting.

Geological Society, Burlington House, Piccadilly, W., 5.30 p.m.

Royal Institution, Albemarle Street, W., 3 p.m. Very Rev. Dean Inge, "Theocracy." (Lecture I.)

THURSDAY, MAY 25. Illuminating Engineering Society, at the ROYAL SOCIETY OF ARTS, John Street, Piccadilly, W., 8 p.m. Annual Meeting.

University of London, King's College, Strand, W.C., 5.30 p.m. Rev. Percy Dearmer, "Central and North Italian Painters of the Fifteenth Century." (Lecture IV.)

5.30 p.m. Prof. F. H. Edgeworth, "The Development of the Head Muscles of Vertebrates." (Lecture IV.)

At King's College for Women, Campden Hill Road, W., 4.30 p.m. Prof. V. H. Mottram, "Metabolism of Fat and Allied Substances." (Lecture V.)

British Architects, Royal Institute of, 9, Conduit Street, W., 5 p.m. Prof. E. A. Gardner, "Greek Public Buildings."

Royal Botanic Society, Inner Circle, Regent's Park, N.W., 6 p.m.

Aeronautical Engineers, Institution of, at the Engineers' Club, Coventry Street, W., 6 p.m. Major Hume, "The Seaplane's Place in Aviation."

Chudwick Public Lecture, Chelsea Physic Garden, Chelsea Embankment, S.W., 5 p.m. Mr. E. A. Bowles, "Superstitions of Early Herbalists."

Royal Society, Burlington House, Piccadilly, W., 4 p.m.

NOTICE.

NEXT WEEK.

WEDNESDAY, MAY 31st, at 3 p.m.
(Ordinary Meeting). LAWRENCE HAWARD,
M.A., Curator of the City Art Gallery,
Manchester, "The Problem of Provincial
Galleries and Art Museums, with special
reference to Manchester." SIR CHARLES
J. HOLMES, D.Litt., F.S.A., in the Chair.

PROCEEDINGS OF THE SOCIETY.

NINETEENTH ORDINARY MEETING

WEDNESDAY, APRIL 5TH, 1922.

LORD HEADLEY, M.INST.C.E.I., in the chair.

The paper read was:—

COAST EROSION AND ITS PREVENTION.

By PROFESSOR E. R. MATTHEWS,
Assoc.M.Int.C.E., F.R.S. (Ed.), F.G.S.

INTRODUCTION.

The author in this paper discusses various matters relating to the encroachment of the sea. He describes certain natural formations which on some parts of our coast protect it from serious erosion, including Sea Beaches and Sand Dunes. He sets out the principal causes of erosion, briefly describing various types of artificial protection works. Reference is made by him to Deep-sea Erosion, the formation of Salt Marshes, Subsidence, and the findings of the Royal Commission on Coast Erosion.

THE COMPOSITION OF THE FORESHORE.

The foreshore and sea bed is usually composed of:—

(1) Rock (as at Troon, Ayrshire) or

(2) Boulders, large and small, either accumulations or isolated boulders or

(3) Shingle, or

(4) Sand, or

(5) Alluvium, or

(6) A mixture of some of the above.

Most of these materials have been derived from denuded cliffs, or, in the case of alluvium, have been brought down by rivers as mud, and accumulated usually in or near an estuary.

NATURAL PROTECTION OF CLIFFS AND LOW-LYING COAST LINES.

The pummelling action of the sea at the toe of a cliff formed of easily-eroded material, say, of clay overlaid with gravel and sand, results in time in the breaking up of the base of the cliff, and the removal by landslip of the gravel forming the top layer of the cliff. This mass of material, clay, gravel, sand and soil (which has fallen on to the foreshore) is immediately attacked by the sea at the next tide, and a sorting out process is carried on; sand and other fine materials are carried off in suspension and deposited some distance away, or rolled along the foreshore by the action of the waves. The larger materials—pieces of clay, boulders and gravel, are forced by the waves up against the base of the cliff, and so form a very small and temporary protection to the toe of the cliff.

FORMATION OF SHINGLE BANKS.

(1) *The Chesil Bank** (Fig. 1).—This world-renowned shingle bank runs parallel to the Dorsetshire Coast, and is the most remarkable bank of shingle around

*"The Grading of the Chesil Beach Shingle," by Dr. Vaughan Cornish, Proc. Dorset Natural History Field Club, 1898.

"On the origin of the Chesil Bank," Joseph Prestwich, Proc. Inst.C.E., Vol. XL.

"Description of the Chesil Bank," by John (afterwards Sir John) Coode, Min. Proc. Inst.C.E., Vol. XII., 1853.

FIG 1.—The Chesil Bank.

our coasts. The bank commences near Abbotsbury, and extends $10\frac{1}{2}$ miles to the Island of Portland, which it joins at Chesilton. At the Portland end, the shingle bank sweeps round in a southerly direction nearly to Blackmore Point. Between the shore and this shingle bank is a sheet of tidal water known as the "Fleet"; this varies in width from a quarter to half a mile. The east end of the bank acts as a natural breakwater to Portland Roads in the east bay.

The average width of the base of this vast shingle mound varies from 600 feet at the east end to 500 feet at the west end. The height of the Portland end above L.W.S.T. is 53 feet, and at Abbotsbury 32 feet. The top is 43 feet and 23 feet respectively above H.W.O.S.T.

In the Dorchester Museum there is a collection of stones taken from this huge breakwater, and they are in the following order of abundance :—

- (a) Chalk flints.
- (b) Greensand chert.
- (c) Portland limestone and chert.
- (d) Quartzites.

The foundation of the bank is Kimmeridge clay at a depth of 8 fathoms of water.

The width of the channel between Plymouth and the coast of Brittany is about 112 miles. This narrows down to 60 miles between Portland Bill and Cap de la Hague, widening to the eastward again to over 100 miles.

This sudden contraction is responsible for the race of Portland on the north side, and the race of Alderney on the south side of the Channel. The velocity of the race off Portland Bill is 5 or 6 knots, and under certain conditions, 7 knots.

"Under the stress of its currents, combined with the blow of heavy gales, the old shingle beach has been steadily pushed

back, and the present contours of the coast line created."*

In 1852 there was a terrific storm, and after this Sir John Coode took numerous sections to see to what extent the face of the bank had moved; these showed that nearly 4 million tons of shingle had been swept down into deep water during this gale.

The bank in normal weather presents a slope of about 1 in $2\frac{1}{2}$, but in severe on-shore gales, the crest assumes a slope of 1 in 9.

The rise of the water at Spring tides is 10 feet.

During heavy gales the waves breaking on the bank, throw the water and spray to a height of 60 to 70 feet, or 20 to 30 feet higher than the top of the bank.

On November 23rd, 1824, a ship was washed completely over the beach on to the Mere side. On September 9th, 1883, the sea broke over the beach, flooding the railway. In more recent years Chesil Street and Victoria Square have been flooded.

The origin of this ancient beach has been the subject of much discussion, and differences of opinion, but it is practically agreed that it could not have been derived either from the few flints produced by the waste of the cliffs near, or from the remains of the older beach which once existed further seaward. "The flints of which the bank is mostly formed denote an inland rather than a sea cliff origin, and point to the time of the breaking up of the last great Ice Age, when the valleys and rivers were scooped out by the ice, and the floods due to its melting, and when vast quantities of rock debris and gravel were carried to the coast."

It is interesting to note that at one time the coast line was 10 miles at least further seaward than at present; this is indicated

* "Tidal Lands," by A. E. Carey, M.Inst.C.E., and Prof. F. W. Oliver, D.Sc., F.R.S.

* "The Sea Coast," by W. H. Wheeler, M.Inst.C.E. (Longmans).

by the line of the old raised beach referred to which stretches across Lyme Bay.

The eroded cliffs contained a large amount of gravel and flints, which, falling on the beach, drifted landwards, forming a bank of increasing magnitude as the cliffs receded. Much of the material was doubtless derived from this source. The bank has, no doubt, reached its maximum size.

At the Abbotsbury end the mean slope is :—

1 in 7 to $3\frac{1}{2}$ fathoms.

1 in 11 to $5\frac{1}{2}$ fathoms.

1 in 30 to 6 fathoms where the shingle terminates.

The bank extends out into the bay at the Chesilton end 200 yards, where the water is 7 fathoms deep.

There are two ledges of rock running nearly parallel with the bank, one at about 5 miles from the shore in 10 fathoms; the other about 10 miles in 15 fathoms.

Sir John Coode tells us that "the stones of which the bank is formed vary very much in size, the largest being at the Portland end. The graduation in size from the east to the west end of the bank is so regular that a Portland fisherman if landed on the bank in the dark would be able to tell his position from the size of the pebbles."

According to Coode large pebbles travel farthest because they move more readily than small ones; Redman agrees to the greater travelling power of the large material as also does Reade. On the other hand, Prestwich, Palmer, Airy, Spratt and Geikie hold that the smaller pebbles travel farthest. The author agrees with this latter contention. The question as to whether the shingle travels east or west on the great Chesil Bank has long been disputed. (Fig. 2.)

FIG. 2.—Movement of Shingle in an Embayment.

The theory accounting for the growth and development of the bank is that the prevailing south-westerly gales and currents bring the largest pebbles eastward, the pebbles dropping in the order of their size, the largest being carried farthest.

The author does not agree with this theory; he suggests that while the travel of material along a coast is almost always in the direction of the flood tide, and the flood tide on this coast is from west to east; yet on a coast indented by numerous bays as is the Dorsetshire coast, the drift in most of these bays is in the opposite direction to the flood tide; the diagram illustrates this.

A glance at the map (Fig. 1) will show the projection southwards of the Bill of Portland and St. Albans Head. These promontories project into the famous Portland Race, which at certain seasons of the year has a travel of seven knots.

The Chesil Bank, where it joins the mainland by West Bay, Dorset, is composed of sand and very small shingle, which gradually increases in size to the westward. If the drift had been east as claimed, the natural result would be the deposit of the larger and heavier stones at West Bay and the lighter ones graduating in size would be carried along until the current was again deflected by the West Cliffs of Portland, and the finer material deposited at Portland end. This, of course, is contrary to the present state. Furthermore, the north end of Portland is clay, and the Chesil Bank is composed of blue clay overlaid with shingle; this being so, is it not to be presumed that before the shingle covering overlaid the clay the heavy sea rollers from the Atlantic would have eroded the clay bank, making a breach and thus making Portland truly an island? On the other hand, if we consider the Race, into which Portland Bill impinges, is it not reasonable to assume that the Cornwall and Devon deposits travelling along with this very strong current, will be deflected by this point of rock and carried into this sheltering bay, first northward and then westward along the West Bay? This procedure would account for the larger material on the beach being at the Portland end.

It has been stated that marked bricks have been put into the sea on the Dorset coast west of West Bay and they have been found again at the Portland end of the beach. The author cannot vouch for this, but, even if it is correct, is it not possible that the bricks may have travelled first westward until drawn into the Race and then carried east until, striking Portland Bill they would be thrown clear of the main current and carried along the cliffs until

they came to rest at the first place suitable ?

It is interesting to note that rudderless ships and sailing vessels in distress generally drift from south of the Bill northwards and travel almost parallel with the Bank, gradually drifting shorewards.

The author agrees with Coode, Matthews and Shield that with off-shore winds, the waves build up shingle beaches, while with on-shore winds beaches are denuded.

"When a small vessel is taken through the Race on Portland Ledge during somewhat rough weather, the decks are covered with sand deposited from the water which splashes over her. The Shambles shoal is undoubtedly maintained by this and other detritus settling from suspension in the repeated horizontal circulation of water eddying round a vertical axis on the east side of Portland."*

ISLAND OF PORTLAND (Fig. 1).

The eastern side is being wasted by the encroachment of the sea, and large portions of the cliff have fallen. About the middle of last century a serious landslip occurred and the cliff for 150 yards in depth fell into the sea.

This Island is composed of oolite limestone containing nodules and bands of chert resting on a bed of grey and yellow sand and Kimmeridge clay.

The highest point (which is some distance back from the Bill) is 488 feet above sea level.

Portland stone is quarried on this Island, and exported to all parts of the country, being used chiefly for building purposes.

The Island is connected with the mainland by a narrow isthmus along which runs the Chesil Bank.

(2) *Dungeness*. This is one of the most wonderful promontories formed of shingle to be seen around our coasts, and its origin may doubtless be attributed largely to the fact that the cliffs at Hastings at one time extended much further seaward than they do at the present time; and the shingle due to wasting back of those cliffs travelled eastward. Mr. Wheeler tells us that "this shingle gradually extended across the mouth of the estuary of the Rother and choked the outlet of the river which finally became diverted from its original course to Rye. The shingle bank thus formed led to the silting up of the estuary of the river, and

the formation of marshes from which the tide was excluded, and the land reclaimed, by the existing artificial banks. The flood tide entering the new outfall eddied round and gradually drifted the shingle in a south easterly direction, and so formed the nucleus of the salient angle which now exists."*

The steady growth of the present shingle bank is due mainly to the shingle travelling on the South Coast in an easterly direction meeting the littoral drift moving along the east and south-east coasts in a westerly direction; these two opposing forces are causing largely the banking up of this shingle promontory as we see it to-day, it is gradually extending further and further seawards, and its face is so steep (2 to 1) that it is said that a large vessel could come near enough to the shore to enable a stone to be thrown on to its deck from the shingle bank.

The base of the triangle forming the headland is approximately 6 miles, and the distance from the base to the apex 3 miles. Since the time of Elizabeth, this promontory has been pushing forward at an average rate of 6 yards a year; the growth in recent years being at the rate of 2.61 yards per year.

The growth of this bank has pushed the harbour of Rye a quarter of a mile further out from the land. On several occasions the lighthouse has had to be moved further seawards. During the past 35 years the shingle has covered 430 acres to a depth of $7\frac{1}{2}$ feet, representing 7,000,000 tons of shingle or 200,000 tons a year. The total shingle deposit covers an area of 6,000 acres.

(3). VARIOUS OTHER EXAMPLES.

(a) At Lancing on the Sussex Coast, there is a shingle bank about a mile long and 150 yards wide.

(b) On the East Coast the Aldeburgh bank extends southwards from Orford Ness for 9 miles, with a width of about 80 yards.

The river Alde once had its outlet to the sea across the marshes to the south of the town. This river (together with the rivers Ore and Butley) has been diverted from its course by the travelling shingle, and its point of discharge is now 9 miles further south than it was originally. At Aldeburgh the river

* "Waves of the Sea," by Dr. Vaughan Cornish (Unwin).

* "The Sea Coast," by W. H. Wheeler, M.Inst.C.E.

is only separated from the sea by a shingle bank 80 yards wide. It is stated that this bank has extended southward more than half-a-mile during the present generation.

The bank suffers most from north-east gales. Probably the only source from which this shingle has been derived is the pebbly gravel contained in the low cliffs 2 miles to the north, and those at Dunwich, 8 miles distant. There is a continuous beach all along this reach of coast, and the direction of the drift is from north to south.

- (c) On the Norfolk coast a shingle bank extends from Weybourne in a westerly direction for 7 miles, terminating at Blakeney harbour. At Weybourne, the bank is about 100 yards wide at the base.
- (d) On the Yorkshire coast a sand and shingle spit projects out into the mouth of the Humber for 3 miles, having a width of from 150 to 200 yards.
- (e) Near Harwich harbour there is a similar spit.

These shingle banks stand out quite separate from the coast line, and have a marked effect upon the configuration of the coast.

- (f) *French example.* Shingle banks may also be seen on the shores of the West of France: in the Bay of Audierne, Finisterre, there is a shingle bank 8 miles in length which extends in a southerly direction from the rocks in the middle of the bay at Penhors to Pennarek. The top of this bank is 16 feet above the beach, and behind it is a salt-water lake and salt marshes. The sea has occasionally broken through, but the gap has been at once restored by the drift of the shingle. The shingle is composed of pebbles of granite, gneiss, mica schist, and quartz derived from the erosion of the adjacent cliffs. The drift and flood tide are from north to south, the prevailing winds being south-westerly.

- (g) *Filey Brig.*—This rocky promontory acts as a natural breakwater, and protects the town of Filey from heavy seas occurring in a northerly gale.

NORFOLK COAST.

- (h) *The Wash.*—Into this estuary the Ouse, Nene, Witham and Welland discharge. These rivers drain 5,820 square miles. This estuary is 12 miles

wide at the mouth and formerly extended 50 miles inland; it had a width of about 30 miles. The Romans, by the construction of over 50 miles of sea banks enclosed the greater part of this area, leaving only the Wash open to the tides.

The area covered by the tides is about 157,000 acres, of which 84,000 acres consist of sand beds dry at low water. These sands, according to old charts prepared in the early part of the last century, have practically retained their shape. Accretion is taking place along the shores of the Wash, especially on the west and south sides.

SAND DUNES.

On many parts of our coasts these may be found, and they form a natural protection. Nine-tenths of the coast line of the world is said to be fringed with sand. In Great Britain there are many square miles of *waste dunes*; these are mostly stationary, but in some places, as on the French coast, and the coast of Holland, there are large areas of shifting dunes which are a menace to the surrounding country, as they destroy in their inland march much fertile land. There is no reason why many of these should not be reclaimed, and in time be made productive. Mr. Gerald O. Case in his "Coast Sand Dunes" gives three ways in which human industry can be applied to coast sand dunes, and the author agrees with his suggestions. They are:—

(1) By forming on a sandy shore where there is now erosion, a protection dune; or one might be formed (on a sandy shore) in front of low lying land for reclamation purposes.

(2) By maintaining a coast protection dune (or dunes) either naturally or artificially.

(3) By reclamation of the landward dune area (which is usually a sandy waste) when the protection dune has been made secure.

There are many examples of reclamation work in sand dune areas at home and abroad. The French particularly have done useful work in this direction. On the Gascony coast of France sand dunes were driven inland by wind action, causing erosion of the coast and ruination to the land. All this has been changed by the work undertaken by the French Government. The success of this work was largely due

to the French engineer, M. Brémontier, who, over a hundred years ago devised a scheme for fixing the Gascony dunes. His scheme consisted :—

- (a) In the formation of a coast protection dune on the shore line.
- (b) In the reclamation of the dunes and sandy wastes on the land-side of this protection sand dune.
- (c) In the cultivation on these dunes of various plants, and later of fir trees.

This work was found in time to be very productive.

On the coast of Lancashire the unblown sand has to a large extent been fixed by vegetation, and erosion prevented, especially in the neighbourhood of Southport; but during the past 300 years the wind has formed a belt of sand from one to four miles wide between Formby and the Ribble estuary. Mr. Case says there is "insufficient vegetation to fix the sand dunes, and they are rapidly moving inland causing large areas of fertile land, and even villages, to be overwhelmed by the advancing sand and sand deserts are formed." *

There are many parts of our coast where reclamation as at Southport might similarly be carried out, and large sand areas which are now only partially protected by vegetation turned into valuable grazing lands.

The Dutch for centuries have realised the value of sand dunes in preventing the inroads of the sea.

It must not be supposed that sand dune embankments raised to their proper height, and fixed by vegetation, are always a cheap and reliable form of coast protection; they will not be at all suitable on some coasts where there is a heavy wave action, and much erosion, but they will undoubtedly stand moderate storms if they are constantly kept in repair. Renewal of the vegetation will occasionally be found necessary, and in many cases it will be found advisable to protect the face of the embankment and occasionally the foundations. This may be done in many ways, reinforced-concrete being found to be a useful material for this purpose.

CAUSES OF COAST EROSION.

Coast erosion is not due to any one particular cause, but to many, some of which may be set out as follows :—

- (a) By the pummelling action of the sea against the base of low-cliffs, and on low coast lines.

- (b) Erosion caused by wind-formed currents acting below L.W.O.S.T.

- (c) By the checking of the alongshore drift, as most harbour projections are doing, including Madras, Lowestoft, Yarmouth, Shoreham, Whitby and others.

- (d) By springs and land drainage discharging down the face of the cliffs, assisted by wave action at base of cliff.

- (e) By landslides, with battering action of sea.

- (f) Rain and frost combined with wave action at base.

- (g) By subsidence of the sea bed.

- (h) Erosion of the bed of the sea due to wave action and currents.

- (i) Removal by builders and others (often including Local Authorities) of shingle and sand from the foreshore.

- (j) Obstructions left on the foreshore.

- (k) Badly designed sea defence works; especially faulty foundations.

- (l) By the owners of adjoining lands doing nothing to stop the erosion in front of their own lands.

- (m) By cutting marram and other grasses from the sand hills, and so removing the protection of the dunes from wind storms.

- (n) By no attempts being made to construct protective works.

(a) WAVE ACTION.

When a wave breaks upon a shore its action is divided into three parts :—

The "plunge;

the "shoreward" rush.

the "backwash" towards the sea.

It is the first of these, the "plunge," that does most damage, the ill effects of the "backwash" being next in severity. The plunge stirs up the sand and shingle, and some of this is rolled along the beach seaward, or, if sand, is carried seaward in suspension; some of the material thus disturbed is rolled forward again by the next breaking wave, and it may be thrown up eventually by the sea or drawn seaward, much of it remaining just beyond L.W.M., and when the next storm occurs it may be lodged permanently at H.W.M.S.T.

It is not the intention of the Author to discuss in detail Wave Action in this paper, but only to refer to it briefly in passing.

Waves occurring in the open sea (as for example in the Atlantic), due probably to a hurricane blowing for several days on

* "Coast Sand Dunes," by Gerald O. Case.

the surface, do no harm to the bed of the ocean, which is miles below its surface, but immediately those waves reach shallow water, say, 150 feet in depth, they meet a shoal. It may now be observed that the water becomes agitated, due to wave action reaching to the bed of the ocean. As it rolls on into still less shallow and lesser shallow water, its action is felt more and more, and it is here that erosion and accretion begin to take place.

Some authorities have suggested that storm waves cannot have any effect on the bed of the ocean even in shallow water, but the author totally disagrees with this view.

(b) EROSION CAUSED BY WIND-FORMED CURRENTS ACTING BEYOND L.W.O.S.T.

While wave action is the principal cause of erosion, the material lying on the bed of the ocean, if the water is not deep, is affected by severe currents. In "Coast Erosion and Foreshore Protection," by Dr. J. S. Owens and G. O. Case, this is explained as follows:—

"The velocity of this translatory movement of water decreases from the surface downwards. When the wind commences to blow, the upper layers of water are drifted with the wind. This forward movement is gradually propagated to the lower 'layers,' and, if the wind continues, eventually produces a movement of the whole body of water, if not too deep. Vice-Admiral Makaroff, of the Imperial Russian Navy, made observations with a current meter on the velocity of the undercurrents in the Bosphorus, in depth up to 22 fathoms, and it appeared that the velocity, and, consequently, the eroding power, decreased progressively as the depth of water increased."*

OBLIQUE WAVES.

Waves striking the shore obliquely, do more damage usually, and remove more shingle, than those produced by a direct on-shore gale. For example, a severe south-westerly gale (continuing for some days) on the South Coast will cause the waves to strike the shore obliquely, and the greatest damage done is always during a gale from this direction. A direct off-shore gale (continuing for several days) often causes a heavy and destructive ground swell in which the waves break with considerable force. On the North East Coast

much damage is sometimes done by such a ground swell.

(c) HARBOUR AND HEADLAND PROJECTIONS.

All seaward projections on a coast, whether they be in the nature of a groyne extending only to L.W.O.S.T., a breakwater, a harbour arm, or a promontory such as Flamborough Head or Spurn, extending seawards some miles, have the effect of checking the along-shore drift, and starving the coast on the leeward side of the projection.

Numerous examples of this might be given, including the cases of Yarmouth, Lowestoft, Whitby, Shoreham, Newhaven, and the glaring example of Madras. Space in this paper will not permit of a description of more than, say, three of these:—

Yarmouth.

Lowestoft.

Shoreham.

YARMOUTH.

This is one of the best examples of a harbour projection extending out into deep water successfully trapping and impounding the travelling sand, while for miles on the leeward side (the travel of material on the east coast is from north to south) the coast has been deprived of its natural protection and become denuded.

This harbour was laid out in its present form between 1660 and 1700.

"Millions of tons of sand have been impounded by the harbour projection, and acres of public gardens laid out on what was formerly a part of the foreshore, and there are many acres of sand which the tide never covers. About 1870 the harbour pier was extended some three hundred feet, and millions of tons of sand have become impounded since then. The trapping of the sand at Yarmouth has meant that for several miles to the south of the town the erosion has been alarming."*

LOWESTOFT.

This harbour was constructed in 1844 and has had a similar effect upon the coast north and south of it. A vast accumulation of sand has occurred immediately north of the harbour, covering an area of about 60 acres, and representing some millions of tons of sand. Large quantities of this are sold annually as ballast, and removed in barges. To the south of Lowestoft at

* "Proc. of the Royal Society of Edinburgh," Vol. XXII.

* "Coast Erosion and Protection," by E. R. Matthews (Griffin).

Pakefield the erosion is most serious, houses having been swept away by the sea.

SHOREHAM HARBOUR.

There is a natural indent in the coast at Shoreham, and a large accumulation of shingle had taken place between the foreshore and the river Adur, before the west pier of the harbour was built in 1874.

Since the pier was extended it has been impossible for any of the material to travel eastwards, and so the already vast shingle bank has grown, and it is now over a mile in length, a quarter of a mile in width, with an average thickness of 30 ft., or, no less than 9 million tons of shingle have accumulated.

The travel along this coast is from west to east, and the heaviest seas occur during south-westerly gales. A good portion of the impounded shingle, were it not for the projecting pier, would travel in an easterly direction affording a natural protection to Brighton and Hove.

FIG. 3.—Headland Projection at 45° with Coast.

HEADLANDS. (See Fig. 3)

This same principle also prevails in regard to headlands; those promontories which project at right angles to the coast more perfectly trap the travel of material along the coast than those running out at an angle in the direction of the littoral drift. Flamborough Head and Spurn are good examples of this. In the case of the former the angle with the coast is 60° , and in the latter it is 25° .

GENERALLY.

The checking of the travel of material on a coast is a most important matter, for not only is material held up by the projection of say a harbour, but the harbour engineer is troubled by the fact that his harbour entrance is frequently blocked by sea-borne sand and shingle, and works constructed at great cost on sandy coasts have been

fearfully expensive in maintaining; as examples we would say that the harbour of St. Catherine in Jersey which was begun in 1848 was subsequently sanded up, and was in consequence abandoned.

A second entrance to Rye harbour constructed by Smeaton, was, in a few years filled by the movement of shingle from the west. The most glaring example is the case of Madras, where the advance of the shore line out-ran the building of the breakwaters. Since this harbour was constructed the accretion of sand on the south side of the harbour has been enormous, and covers an area of 260 acres, while alarming erosion has been and is, taking place on the north "leeward" side of the harbour, and villages have been swept away by the encroaching sea.

During a storm at Port Said which continued for one or two days, about two million cubic yards of sand was deposited in the mouth of the channel; the available depth being reduced by 8 feet.

(d) SPRINGS AND LAND DRAINAGE.

Good illustrations of this are seen on many parts of the Holderness Coast of Yorkshire, and in the Cliffs between Walton-on-the-Naze and Frinton. The coast line just to the north of Bridlington also affords an excellent example of this.

(e) LANDSLIDES.

On many parts of our coast *landslips* are of frequent occurrence. One of the best examples the author has seen is in the Crag Cliffs near Walton-on-the-Naze. The Crag rests on a flat bed of London clay the level of which is about shore level, and the subsoil water in the Crag percolating down to the clay bed assists in this sliding action. Rain and frost, combined with wave action at the base of the cliff, assist considerably in this destruction.

(g) SUBSIDENCE.

The author has for some years been of the opinion that the sea bed, and most of our river valleys, are gradually subsiding. The land about the Mersey estuary has sunk during historic times; evidence of this is shown in the gradual rise of mean tide level at Liverpool.

Many evidences of subsidence might be given, but only two will be named.

- (1) The remains of ancient docks 27 feet above the seal level may be seen in Crete.

- (2) In some districts coal is being mined at depths of 3,000 feet below the level at which plants must have grown.

In spite of these and many other suggested proofs we find eminent geologists, such as Mr. Clement Reid, F.R.S., saying in his evidence before the Royal Commission on Coast Erosion that in his opinion:—"The rise of the sea level (*i.e.*, the subsidence of the land) may have been completed about 3,500 years ago, and only then commenced the coast erosion which we now see."

He also said that:—"About 3,500 years ago we get back to the beginning of the period of unchanging sea level in which we are still living."*

Other well-known geologists seem to support Mr. Reid's contention. Professor W. Boyd Dawkins, for example, in 1903, said he did not know of any depression of the coast line or changes of level in any part of the country that had not taken place before Roman times, and Mr. W. Whitaker, F.R.S., F.G.S., told the Royal Commission that he had no good evidence of movements now going on.

So there are conflicting views on this important subject.

Huge upheavals and depressions, of course, have occurred as a result of severe earthquake shocks; take the well-known Lisbon earthquake of 1755, when the site of the harbour sank 600 feet. The most striking example in recent times of upheaval was the raising of the beach at Yakutat Bay, Alaska, from 7 feet to 45 feet, in 1899.

In 1845 a wooden bridge was discovered near Birkenhead (presumably Roman), spanning a tributary of Wallasey Pool; the roadway of this bridge was 14 feet below the level of high tides.

"The existence of old roads running down to the sea at Seaforth, Crosby, and on the New Brighton Coast were apparently objectless, unless they at one time crossed the bed of the estuary."†

Evidences of depression are also to be found in submerged forests at various parts of the coasts of England; the author has seen a number of these. In the Alexandra Park at Hastings, for example, there is a tree trunk which came from a submerged forest some distance seaward of the outer end of the Hastings Pier. In their "Coast Erosion and Foreshore Protection," Dr. J. S. Owens and Mr. Gerald O. Case say they

came across beds of peat six feet thick on the foreshore at Youghal, Ireland, with branches and trunks of trees embedded. At Deal, also, and on some parts of the Norfolk coast peat is to be found under the foreshore.

"During the excavations for the docks at Hull a forest was found at a depth of about 40 feet below high water, and in the Finlands some five buried forests have been discovered."*

(h) DEEP-SEA EROSION.

Evidence of deep-sea erosion may be seen on almost any shore after a storm in the form of large stones with lengthy seaweed attachments. Such stones have been wrenched by storm waves from the rocky bed of the ocean and flung up on the shore; especially does this occur during on-shore gales. Coast erosion can often be remedied, but deep-sea erosion cannot.

(i) REMOVAL OF MATERIAL FROM THE SHORE.

On some parts of our coast limestone and other stone has been allowed to be removed from the foreshore; this practice has not yet entirely stopped. In one year as much as 10,000 tons of limestone were taken from the cliffs and ledges near Lyme and exported to Hull. Many examples might be given as to the acceleration of erosion due to the removal from the foreshore of sand and shingle.

(j) OBSTRUCTIONS ON A SHORE CAUSING EROSION.

It is a very unwise thing to place upon the shore any obstruction with a view to preventing erosion, or with the object of breaking up the waves; many such obstructions may be found around our coasts. At Preston (near Weymouth) a long line of heavy rocks were deposited upon the sea bed at L.W.M., the result being that they were so detrimental that they had eventually to be blasted away. Another example of this practice is to be found at Bridlington, Yorkshire; the sea wall (see Fig. 4) protecting the spa was built a few feet shorewards of the ruins of a previous sea wall, and the result has been that scouring action has taken place. The remains of old groynes and breakwaters are often left on the foreshore. At Troon, in Ayrshire, where the author carried out a sea defence scheme, he found it necessary to build a

* "The Evolution of a Coast Line," by William Ashton.

† "The Evolution of a Coast Line," by William Ashton.

* "Geological Journal," Vol. LX., p. 101.

FIG. 4.—Erosion caused by obstructions at Bridlington (South Shore)

new sea wall some distance seaward of the old one, in order to avoid the huge rocks which stood up above the foreshore (see Fig. 5).

FIG. 5.—Obstruction on a Rocky Shore—Troon, Ayrshire.

(3) (a) It is not intended in this paper to describe the extent of the erosion around our coasts, or the amount of accretion that is taking place on other parts of the coast, as these have been so often dealt with. The causes of erosion are more interesting to the readers of this paper, and the suggested best methods of remedying it.

(a) PROTECTION DEVICES.

Many devices for the prevention of erosion have been introduced, but most of these have proved a failure. Floating breakwaters anchored to the shore, large rocks, and in some cases huge blocks of concrete, specially arranged on the foreshore (below and above L.W.O.S.T.), with a view to breaking the force of the waves, have been

tried with the object of protecting the shore, but most of these have created a scour and have done much damage instead of good. Rows of piles have sometimes been driven parallel with the shore and a few feet seaward of the cliffs or sea wall, but most of these have been quite unsuccessful.

Dr. Owens suggests that shore protection works might be divided into active and passive types; the former comprising groynes and such structures as attempt to do something more than merely resist attack; the latter, including sea walls and embankments, which only attempt to substitute a harder and more durable material for a softer. Following this course, we will next discuss "groynes."

METHODS OF PREVENTION OF EROSION.

(b) *Groynes*.—Some engineers avoid the construction of groynes in a scheme of sea defence, and only adopt them as a last resource. The author's experience has taught him that the erection of a sea wall, or other form of sea defence running parallel with the coast, is of itself usually insufficient and often increases the erosion on the shore, and, for the purpose of collecting and retaining beach or sand in front of a sea wall, and, incidentally, in protecting the wall against scour by the sea, it is necessary to construct in many (but by no means all) cases a system of groynes. On the other

hand, groynes without a sea wall or other form of sea defence at, say, the foot of an easily-eroded cliff, will generally be of little use.

Great care should be taken in the choice of the type of groyne to be erected, and of the material of which it is to be constructed; reinforced-concrete, timber, mass-concrete or concrete blocks are in general use. It must be remembered that what would be a great success on one part of our coast might be a failure on another part.

Then with regard to the *height* of groynes, serious results and great erosion have been caused by constructing very high groynes where low ones should have been introduced. On the South Coast the high groyne has been largely adopted, and the author does not at all favour its use. (See Fig. 6).

FIG. 6.—Low Timber Groyne with Stays.

Mr. E. Latham, in his "Maintenance of Foreshores," informs us that:—

"At a well-known pleasure resort on the South Coast, the high groynes erected by the Corporation have arrested the beach travel, and now protect the lower parade, but the effect on the sewage outfall situated on an adjoining promontory within the boundaries of the borough has been disastrous, the outfall works having been denuded of their original protective shingle formation."*

TYPES OF GROYNES.

Timber Groynes.—No standard type of groyne can be introduced which would be suitable for any part of our coast.

Where there is an abundant quantity of shingle on the foreshore, and the shore is rocky, concrete groynes (if not high) are suitable; these should be stepped down to suit the gradient of the foreshore and keyed into the rock. On a flat foreshore where sand overlies say, clay, low timber groynes

extending to L.W.O.S.T., are useful; high timber groynes should not be introduced, and the type of timber groyne the author has sometimes adopted and which has proved very satisfactory is shown in Fig. 6.

This type of groyne may be described thus:—It consists of a double row of 9in. by 9in. piles with 9in. by 9in. anchor piles. The former are 14 feet long, the latter 8 feet, penetrating into the clay to a depth of 6 feet. The stays are 10in. by 5in. The planking is 11in. by 4in., and is inserted between the pairs of piles, which are shod with 28lb. shoes. The stays are only inserted at every third set of piles, and the main piles are pitched 7 feet apart, beginning and ending with a set of stays. On some parts of our coasts, where wave action is not severe, this type of groyne can be used minus the stays, but it is wise in most cases to insert them. Groynes of this type should be carried to L.W.O.S.T. (See Fig. 7).

REINFORCED-CONCRETE AND MASS-CONCRETE GROYNES.

The disadvantage of using timber in the construction of groynes is that the material is not durable; this, however, in the author's opinion, has been somewhat exaggerated in this country: for example, 20 years ago when Borough Engineer of Bridlington, the author constructed a system of low timber groynes (17), on the north side of the harbour, somewhat resembling the "Case" system; these have proved very successful, and are in as good a condition to-day as when put down. They consist of 9in. by 9in. piles (Pitch pine) placed in pairs with 11in. by 4in. planking fitting in between the piles. The piles were 14 feet long and placed 7ft. 6in. apart. They penetrated into the clay to a depth of 8 feet, and were so arranged that the planking could be raised or lowered as the beach accumulated. When the author inspected these groynes in September last most of the planking was entirely buried in the sand, and only the tops of many of the piles could be seen. The good condition of these groynes is due, no doubt, to the fact that they were constructed on a sandy foreshore, and that there was little attrition of shingle as there would have been on a foreshore of beach.

It must be admitted that on some parts of our coasts where there is shingle, and attrition is very great, timber suffers severely

* "Maintenance of Foreshores," by Ernest Latham, M.Inst.C.E.

FIG 7.—High Timber Groyne

and groynes of a more durable character should be introduced ; to meet this demand the "Owens-Case Reinforced-Concrete Groyne" has been constructed on various parts of our coasts, and in most cases has proved very successful. On a sandy shore they are quite satisfactory, but sometimes on a shingle shore where wave action is most severe (as on the South Coast), the attrition of pebbles is considerable, and a slight wearing of the edges of the piles is visible. It is difficult to prevent this entirely, but this defect is being overcome very largely in the Owens and Case groynes now being constructed. Groynes of this type can be constructed at a fairly reasonable sum where there is an abundance of shingle as aggregate for the concrete.

In constructing groynes of this type great care should be exercised in the driving of the piles, as, unless they are very accurately spaced it is difficult to insert the R.C. slabs.

Heavy mass concrete groynes, or concrete groynes faced with concrete-blocks, or basalt, or other stone, and extending from a sea wall to the foot of, say, a steep beach, are useful sometimes (especially on a rocky shore), or where wave action is most severe, as, say, on the South Coast at Hastings, but these should be kept as low as possible, and the author recommends the construction from the bottom of the beach to L.W.O.T. of a low timber groyne. It is very doubtful if any other type of groyne than the concrete or concrete-block type would have been suitable at Hastings, where the range of the tides is so great (25 feet), and wave action during a South-Westerly

gale so severe. Timber groynes on the beach slope would have been of little use, and even reinforced concrete groynes would not have been so suitable as concrete-block faced low groynes. At Brighton, the Owens Case R.C. groyne has been installed, and seems to be giving every satisfaction, regardless of the fact that the beach material contains so many sharp flints.

With regard to very high timber groynes, as in use at Eastbourne, these are not only unsightly and dangerous to young children using the shore, but are of little use as "groynes," and have occasionally to be scuttled in consequence of the large accumulation of shingle on the windward side.

It is a useful practice when designing timber groynes, so to arrange them as to allow two bays near H.W.O.S.T. to be adjustable, so that the planks above the shore level can be removed easily, and the impounded shingle in the angle formed by the groyne and sea wall carried through the opening into the next bay where the shore is probably denuded. A good example of this may be seen at Clacton.

GENERAL NOTES ON GROYNES.

The main use of groynes is to arrest the drift of material ; they cannot of themselves afford protection to the coast, neither should they be constructed as breakwaters to modify wave action, except in unusual cases.

No definite rule can be applied as to the distance apart that groynes should be placed. As a rule, it is wise to carry long low timber groynes to L.W.O.S.T., but this cannot always be done.

Direct on-shore gales usually denude the beach, but groynes will not prevent this.

On shingle beaches the movement of material is greater than on sandy beaches ; a banking up of material on the windward side of the groyne will, therefore, be greater where there is shingle.

The running out of an open jetty some distance seawards of L.W.O.S.T. usually causes an accumulation of sand or shingle on the windward side of the jetty. At Ymuiden harbour, for example, this has occurred.

It is sometimes possible for a single groyne to protect quite a long length of coast ; on the other hand, if the groyne is a "high" one, and is carried to L.W.O.S.T., it may mean that a considerable banking up of shingle will occur on the windward side, and the beach be denuded on the lee side for perhaps a mile. The author's advice was sought in a case like this recently.

Groynes should be sloped off to the angle of the foreshore, or stepped, and, speaking generally, they should not be higher than, say, three feet above the foreshore. The best direction for groynes is slightly in the direction of the heaviest seas.

Faggots.—Probably the cheapest form of sea defence to be found around our coasts, are faggots, inserted in the beach usually at about H.W.O.S.T., for the purpose of holding the beach or sand ; this is usually fairly successful if carefully watched, and immediately repaired should a breach occur. It is, nevertheless, only of a very temporary character.

Good examples of this form of defence may be seen on the coast line between Pevensy and Bexhill, and in the case of a sandy shore, at Skegness.

(To be continued)

THE BUILDING-MATERIALS INDUSTRY IN CZECHOSLOVAKIA.

The building materials industry in Czechoslovakia occupies a very prominent position among the industries of the country. Its importance is due to the rich deposits of kaolin, clay, limestone and coal with which Czechoslovakia is naturally endowed.

Owing to the favourable supply of raw materials the brick industry is one of the oldest in the country. There are more than 700 brick works, the most extensive being that of Hodonin, which produces 60 million bricks or tiles per annum. The number of workmen employed in the brick industry amounts to 80,000 and the

annual output is about 2 billion bricks and 200 million tiles.

Kaolin constitutes one of the most important factors in the development of the paper, porcelain, and pottery industries. The largest kaolin deposits are located in the districts of Plzen, Podborany, Karlovy Vary and Western Slovakia. The annual capacity of output amounts to more than 20,000 waggons, of which 80 per cent. is exported. The bulk of this exported kaolin, about 75 per cent. in all, is purchased by Germany, where this product is indispensable. The remainder is distributed between Austria, Poland, Yugoslavia, Hungary, Switzerland, France and Italy. Czechoslovakia contains 30 large kaolin mines, and several hundred smaller ones. English kaolin is the most considerable competitor of the Czechoslovak product.

Porcelain is produced in 70 factories, especially in the kaolin districts of Western Czechoslovakia. The annual output exceeds 3,000 waggons, 70 per cent. of which are exported. The bulk of the luxury porcelain is sent to the United States, Great Britain and Germany ; white porcelain to America, India, Italy and Yugoslavia ; technical porcelain to America, Italy, Switzerland, England, Germany and Rumania. The most extensive customers for these goods are America and the Balkan countries.

The most important centres for the manufacture of fireproof goods are located in the West of Bohemia, Prague, Southern Bohemia, Central Moravia, Lower Slovakia, and Carpathian Ruthenia. The output of the magnesite mines of Lower Slovakia is largely exported, for the most part to America. Czechoslovakia produces annually 40,000 waggons of fire-proof bricks which are exported to all European countries, as well as to overseas countries.

The annual output of pottery amounts to 2,000 waggons. The export trade is with the Balkan countries, Poland, France, the Netherlands, Scandinavia and South America, competition being carried on in this branch with England and Germany. There are 60 factories producing an annual total of 5,500 waggons of stone and chemical piping. The export trade, which comprises 4,100 waggons, is with southern eastern and northern Europe, its most considerable competitor being that of Germany.

The Czechoslovak flagstone industry is carried on in 12 factories with an annual capacity of 9,000 waggons. In 1920 the total amount exported was 7,728 waggons, although the factories were not working at their full capacity.

Another export product is artificial Portland Cement, obtained from 12 factories with a total annual capacity of 50,000 waggons. The export trade is with Germany and Austria.

The annual production of limestone amounts to 90,000 waggons, 10 per cent. of which is exported. The chemically purest limestone is found at Koneprus, near Beroun. The hydraulic

limestone of Prague used to be exported largely to France, Italy and England.

Among the natural building-stones there are numerous types of granite. Special reference may be made to those of Benesov, Jindrichuv Hradec, Petrograd, Blatna, Skutec, Hlinsko and Silesia.

Sandstone rocks are found at Horice, Decin and elsewhere. Czechoslovak marble is being more and more exported. The largest red and grey marble quarries are at Sliveneec, near Prague. White marble is found in Silesia. The export of natural building-stone in 1920 amounted to 1,800 waggons, the countries to which it was sent being Germany, Hungary, Poland and Jugoslavia.

The Czechoslovak building-materials industry forms a group of the Federation of Czechoslovak Industrialists. The problems affecting this industry are studied from a scientific and practical point of view at the Prague and Brno polytechnic schools and the Masaryk Academy. There are also special schools at Bechyn, Znojmo and Teplice for pottery, at Plzen for brickmaking, and at Horice and Supinkovice for stone-cutting respectively.

MEETINGS OF THE SOCIETY.

ORDINARY MEETINGS.

WEDNESDAY, MAY 31 (at 3 p.m.)—LAWRENCE HAWARD, M.A., Curator of the City Art Gallery, Manchester, "The Problem of Provincial Galleries and Art Museums, with special reference to Manchester." SIR CHARLES J. HOLMES, D.Litt., F.S.A., Director of the National Gallery, in the chair.

INDIAN SECTION.

FRIDAY, JUNE 23 (at 4.30 p.m.)—F. W. Woods, C.I.E., late Chief Engineer, Irrigation Department, Punjab, "Irrigation Enterprise in India." LORD LAMINGTON, G.C.M.G., G.C.I.E., Governor of Bombay, 1903-7, in the chair.

DOMINIONS AND COLONIES SECTION.

FRIDAY, JUNE 9, at 4.30 p.m.—MAJOR SIR HUMPHREY LEGGETT, D.S.O., R.E., "Tanganyika Territory (formerly German East Africa)." RIGHT HON. SIR FREDERICK D. LUGARD, G.C.M.G., C.B., D.S.O., in the chair.

MEETINGS OF OTHER SOCIETIES FOR THE ENSUING WEEK.

- MONDAY, MAY 29.—British Architects, Royal Institute of, 9, Conduit Street, W., 8 p.m. Mr. W. Harvey, "Colour in Architecture."
Victoria Institute, Central Hall, Westminster, S.W., 4.30 p.m. Rev. J. E. H. Thomson, "The Readers for whom the First Gospel was Written."
Geographical Society, 135, New Bond Street, W., 5.30 p.m. Anniversary Meeting. Presidential Address and Presentation of Medals.
University of London, University College, Gower Street, W.C., 5 p.m. Mr. A. T. Walmisley, "Groynes and Sea Defence Works."
5.30 p.m. Prof. T. Borenius, "Past History of Art Teaching."
Chemical Industry, at the Institute of Mechanical Engineers, Storey's Gate, S.W., 8 p.m. Sir George Bellby, "The Structure of Coke: its Origin and Development."
- TUESDAY, MAY 30.—Photographic Society, 35, Russell Square, W.C., 7 p.m. Mr. E. J. Bedford, "Wild Flowers."
Anglo-French Society, Scala House, Tottenham Street, W., 6.15 p.m. M. Maurice Thiéry, "Le Théâtre d'Amour, Georges de Porto Riche."
Royal Institution, Albemarle Street, W., 3 p.m. Sir Percy Sykes, "Twenty-five Years' Travel in Persia." (Lecture I)
University of London, King's College, Strand, W.C., 5.30 p.m. Dr. D. Subotic, "Influence of Geography on the Economic Conditions of Jugoslavia." (Lecture I.)
5.30 p.m. Mr. C. E. M. Joad, "Vitalism Restated." Lecture I: "The Reduction of Ethics in Psychology."
- WEDNESDAY, MAY 31. People's League of Health, at the ROYAL SOCIETY OF ARTS, John Street, Adelphi, W.C., 6 p.m. Mr. R. R. Hyde, "The Country's Needs and how to meet them through Health in Relation to Industry and Commerce."
Literature, Royal Society of, 2, Bloomsbury Square, W.C., 3.30 p.m. Anniversary Meeting.
University of London, King's College, Strand, W.C., 5 p.m. Dr. A. Harker, "Geology." (Lecture III.)
- THURSDAY, JUNE 1. Royal Institution, Albemarle Street, W., 3 p.m. Very Rev. Dean Inge, "Theocracy." (Lecture II.)
University of London, King's College, Strand, W.C., 5.30 p.m. Rev. Percy Dearmer, "Central and North Italian Painters of the Fifteenth Century." (Lecture V.)
At King's College for Women, Campden Hill Road, W., 4.30 p.m. Prof. V. H. Mott-ram, "Metabolism of Fat and Allied Substances." (Lecture VI.)
Linnean Society, Burlington House, Piccadilly, W., 5 p.m. "Hooker Lecture by Prof. Seward."
Royal Society, Burlington House, Piccadilly, W., 4 p.m.
Chemical Society, Burlington House, Piccadilly, W., 8 p.m. (a) Messrs. J. S. Buck and I. M. Heilbron, "The reactivity of Doubly-conjugated Unsaturated Ketones." (Part III.: "Unsymmetrical Hydroxy- and Methoxy-derivatives.") (b) "Phenopyryllium Salts of Diaryl Ketones." (Part I.)
Engineers, Junior Institution of, at the Institution of Electrical Engineers, Savoy Place, Victoria Embankment, W.C., 7.30 p.m. "Canet" Lecture by Sir Eric Geddes.
- FRIDAY, JUNE 2.—Royal Institution, Albemarle Street, W., 9 p.m. Hon. Maurice Baring, "Gilbert and Sullivan."
University of London, King's College, Strand, W.C., 5.30 p.m. Mrs. Rosa Newmarch, "The National Opera of Czechoslovakia." (Lecture I.)
Philological Society, University College, Gower Street, W.C., 8 p.m. Dr. Henry Bradley, "Dictionary Evening."
- SATURDAY, JUNE 3.—Royal Institution, Albemarle Street, W., 3 p.m. Sir Hugh Allen, "Early Keyboard Music." (Lecture II.)

Journal of the Royal Society of Arts.

No. 3.628

VOL. LXX.

FRIDAY, JUNE 2, 1922.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C. (2)

NOTICES.

NEXT WEEK.

FRIDAY, JUNE 9th, at 4.30 p.m. (Dominions and Colonies Section.) MAJOR SIR HUMPHREY LEGGETT, D.S.O., R.E., "Tanganyika Territory (formerly German East Africa)." THE RIGHT HON. SIR FREDERICK LUGARD, G.C.M.G., C.B., D.S.O., in the Chair.

TWENTY-THIRD ORDINARY MEETING.

WEDNESDAY, MAY 24th, 1922; SIR GEORGE T. BEILBY, D.Sc., LL.D., F.R.S., Director of Fuel Research, in the Chair.

The following candidates were proposed for election as Fellows of the Society :—
Beall, F. F., Detroit, Michigan, U.S.A.
Doyle, William, B.A., Loughborough
Javeri, Ratilal C., London
Kilachand, T., London.
Mukherjee, Tarak Nath, Howrah, Bengal, India

Palairat, Charles R., Indore State, India
Small, Frank S., B.Sc., New York City, U.S.A.

The following candidates were balloted for and duly elected Fellows of the Society :—
Howgrave, Walter, Addiscombe, Surrey.
Marshall, Henry, M.S.A., Calcutta, India
Muirhead, Alexander, C.I.E., London.
Pearson, Nels August, Rancagua, Chile.

A paper on "The Natural Power Resources of Ireland (Coal, Peat, Water Power)" was read by Mr. GEORGE FLETCHER, Department of Agriculture and Technical Instruction for Ireland.

The paper and discussion will be published in a subsequent number of the *Journal*.

INDIAN SECTION.

FRIDAY, MAY 26th, 1922; THE RIGHT HON. VISCOUNT PEEL, G.B.E., Secretary of State for India, in the Chair.

The Sir George Birdwood Memorial Lecture on "Indian Painting and Muham-

madan Culture," was delivered by Sir Thomas W. Arnold, C.I.E., D.Litt., M.A., Professor of Arabic, School of Oriental Languages.

The lecture will be published in a subsequent number of the *Journal*.

PROCEEDINGS OF THE SOCIETY.

NINETEENTH ORDINARY MEETING

WEDNESDAY, APRIL 5th, 1922.

LORD HEADLEY, M.Inst.C.E.I., in the chair.

COAST EROSION AND ITS PREVENTION.

By PROFESSOR E. R. MATTHEWS, Assoc.M.Inst.C.E., F.R.S. (Ed.), F.G.S.

(Continued from page 489)

(c) SEA WALLS.

The author has already said that groynes are not intended to prevent erosion so much as stopping the drift on a shore. To protect low-lying land from the inroads of the sea, or to prevent erosion of cliffs, it is necessary, in most cases, to construct a permanent form of sea defence running parallel with the shore; this is usually a sea wall, or an embankment; a system of groynes is, in most cases, required as well. Space in this paper cannot be found for a description of the various types of sea walls met with around our coasts; they vary considerably on different parts of our coasts, some being step-faced, as at Bridlington (Royal Princes Parade), others curved-faced, as at Scarborough (Marine Drive), a few sloping, as on many parts, particularly the South Coast, and a number vertical. The merits and demerits of each of these types of walls have been the subject of much discussion.

Then, as to the materials of which they are constructed. Some are stone-faced (including basalt), others are faced with concrete blocks or flints, while quite a number are of mass concrete.

There are also around our coasts a few examples of reinforced-concrete sea walls.

With regard to "vertical" and "sloping" walls, these are most useful as harbour walls, and especially the vertical wall, but they are not so serviceable for coast protection.

A comparison between harbour walls and those intended to protect the coast is scarcely fair, because a sea-wall has to act as a retaining wall as well as resist the force of storm waves. The author has recently designed a sea-wall which is surcharged by a cliff 80 feet high, and the thrust on the wall is considerable (see Fig. 8). In the case of a

(2) The force due to the momentum of a wave moving with great velocity and being suddenly stopped.

(3) The statical pressure due to the head of water brought against the wall by the upward projection of the waves.

Mr. Wheeler suggests that "the strongest part of the wall should be at the point where the wave changes from the horizontal to the vertical position."*

It is very necessary that whatever the profile of the wall may be a heavy projecting cornice should be inserted to throw back the wave, and so prevent it from leaping the wall, and falling heavily upon the road or promenade at the back; much damage is often done in this way. The author has often seen concrete on a promenade broken up like pie-crust, and on one occasion he

FIG. 8.—Mass-Concrete Sea Wall (where stone facing or concrete-block facing is too expensive).

breakwater running out from the shore there is equal water pressure on both sides of it, except during a storm when the waves strike the wall with tremendous force.

NOTES IN GENERAL ON SEA WALLS.

Three forces act on a sea wall:—

(1) Earth pressure at the back of the wall.

saw the whole road at the back of a sea wall drop 3 or 4 feet after a violent storm. Undoubtedly the best form of wall is the stepped-face with concrete backing where stone can be obtained at a reasonable cost. Walls of this type were con-

* "The Sea Coast," by W. H. Wheeler. M.Inst.C.E.

structed by the author at Bridlington a few years ago; they need no description; they have answered their purposes well, and their chief advantage is that the stepped-face quite breaks up the wave as it strikes the wall; the sea falling down the steps with much less velocity than in the case of the smooth-faced wall, little scour at the base of the wall occurs.

It is quite possible to face the wall with concrete blocks and step it in a similar way.

FAILURES OF SEA WALLS, WHY?

A large proportion of the failures of sea walls is due to:—

- (a) The sea getting at the back of the wall, often through displacement of a portion of the surface of the promenade, or by flooding during abnormal tides.
- (b) No projecting cornice having been inserted to throw back the wave.
- (c) The sea undermining the foundations through these not being carried deep enough.
- (d) The wall being too low, or too light in section.

THE ISLE OF WIGHT PERIL.

General J. B. Seely, a few months ago, drew attention in the papers to the fact that there was a likelihood that in course of time, the Island might be cut in two by the inroads of the sea, and the author agrees with him. The part of the Island where the sea might perform this is Freshwater, which is inadequately protected. All that the sea would have to do would be to surmount a shingle beach protected for a part of its length by a concrete esplanade about 8 feet high.

Behind this wall, and only about 50 yards from it, is the source of the Yar which is only a foot or two above sea level.

Should an exceptionally high tide occur at Spring tides, during a violent south-westerly gale, the sea might surmount the low barrier, and run down the valley of the Yar to the Solent at Yarmouth, thus completing the severance.

Most of the esplanade at Freshwater is now in ruins as the result of the heavy seas this winter, and it has been decided to demolish the remaining portion, and to build new sea defence works. It is hoped that the Government will contribute substantially to the cost of these works, and the Royal National Lifeboat Institution, the author understands, has promised to bear

part of the cost if a Lifeboat station can be established there: the remainder of the cost will no doubt be met by the Local Authority.

SALT MARSHES.

The growth of salt marshes in this country occurs almost always in river estuaries, and at the mouth of rivers which are sheltered from wave action. They are formed in the following manner:—

The upper soil of which the marsh is composed is deposited about the time of H.W.S.T. Up to the level of H.W.N.T. sand and silt only are deposited, the fine warp in which the marine grasses of the salt marshes grow is never deposited below the level of H.W.N.T.

In England large areas of marshes have been formed in the river estuaries from alluvial matter brought down in suspension. They have been reclaimed from the sea by embankments, and some form valuable agricultural land.

AMERICAN EXAMPLE.

On the East Coast of the United States, the largest area of salt marshes in the world is to be found; they cover an area of hundreds of square miles, and most of this area is covered by only one or two feet at high water. Mr. Shaler (in his "Sea and Land") estimates that "along the coast South of New York, there are not far from two million acres of marshes fit for reclamation, and which, owing to the small rise of the tide (which does not exceed from 4 to 5 feet) and in consequence of the banks already formed by the sand along nearly the whole length, could be enclosed at a comparatively small expense."*

One of the greatest reclamation schemes brought forward in England was for the reclamation of 150,000 acres of land in the Wash. This scheme received the sanction of the Government, and was supported by a number of eminent engineers, but was never carried out, although numerous much smaller schemes were subsequently carried out. Much of the land included in the big scheme was, however, quite unfit for reclamation.

COAST EROSION COMMISSION REPORT.

In 1912 the Report of the Commissioners was published, and many were surprised to find that the land was giving back more

* "Sea and Land." by N. S. Shaler (Smith, Elder & Co.).

ground to the seaboard than was taken away by erosion; but, the author would point out, nearly all of this occurs in estuaries, and most of it is sediment brought down by the rivers and deposited in estuaries, and cannot be compared with the valuable agricultural land washed away. Many thousands of acres of this reclaimed land is only marsh land of little, if any, value.

Then it is of little satisfaction to a land

Ministry, suggesting that the time was opportune, owing to the large number of unemployed, for the Government to take in hand the protection from the inroads of the sea of certain parts of our coasts where erosion was most serious and that this be done on a contributory basis. The basis that the author suggested was that on a part of the coast where erosion was severe (as on the Holderness Coast of Yorkshire)

FIG. 9.—Erosion on Holderness Coast of Yorkshire (11 feet per annum).

owner on say, the East Coast, to know that the land which he has lost has re-appeared in some estuary.

The Commission admitted that the gains were in tidal estuaries, but the losses were on the open coast.

The largest gains around our coasts are at Southport, in Morecambe Bay; and in the Wash. Between Preston and Southport 7,400 acres have been reclaimed within the past century. On the east coast the loss is very much more than the gain if the accumulations in the Wash and Humber are disregarded.

In June 1912 it was stated in Parliament that a Bill was in preparation dealing with the Coast Erosion Commission's Report, but so far nothing more has been heard of this.

COMMUNICATION FROM MINISTRY OF AGRICULTURE AND FISHERIES.

The author wrote a few months ago (at the beginning of this winter) to the above

(See Fig. 9), and where the land was only poor quality agricultural land, and the owner was not able to afford to protect it, not even by constructing a system of groynes, the Government should carry out the necessary protection works on the following financial arrangement:—

That the landowner should contribute one-third of the cost of protection, the Rural District Council and the County Council (combined), say, one-third of the cost, and the Government one-third. The author believes that such an arrangement would prove satisfactory.

The reply received was to the effect that the Ministry had recently had this question under consideration, but they had decided to take no action, as the problem of housing and feeding large numbers of men at these isolated parts of our coast, especially during the winter months, presented considerable difficulty. They also

reminded the author that the Royal Commission had decided that works for prevention of coast erosion must be regarded as a local, and not a national matter. Under these circumstances they intended to take no action in the matter.

The writer is indebted to the authors of the various works referred to in this paper, for the quotations he has made from their books, and to Mr. T. Henry Tyson, the Borough Engineer of Portland for much valuable information regarding the Chesil Beach.

DISCUSSION.

THE CHAIRMAN (Lord Headley), in opening the discussion, said in sea work there was great difficulty in getting sufficient data to enable one satisfactorily to cope with questions which arose. The first thing was to interview the oldest inhabitant, and find out what had been the highest tide within living memory in the particular locality. That information was not all that was required, because at any time there might be a very difficult combination of an exceptionally high tide, accompanied by a most disastrous wind. One of the greatest difficulties was that often a sufficiently large amount of money could not be spent because the clients could not afford to pay it. Too light a protection must not be used, because if the combination to which he had referred produced bad results the engineer would be blamed. At a place on the Southern Coast of Ireland he was called in, and after examination suggested a simple plan for the adoption of low groynes, and the cost was very little—£1,500 or £1,000. The authorities said: "We are very sorry we cannot do that; we will give you £200 to put in one groyne, and if that is a success, we will let you go on." He replied: "You will only get one result by putting in one groyne, and that may be disaster, because you will find that the sea will make an inroad at some portion of the coast close to that groyne. You must treat the shore as an entire piece, or else let it alone altogether." It was a legal maxim that a man must not, in order to protect himself or his property, resort to devices which injured his neighbour's property. That was a most important matter in regard to coast protection. It was impossible to erect an obstruction, or sea wall, or jetty, without altering the conditions along the coast line. All the currents were altered, and the effect could not be foretold. Engineers of the greatest eminence had been considering the question of extending the Admiralty Pier at Dover for about 150 years, and the result of all their work had been that Dover Harbour was not satisfactory. Sailors had said to him: "You cannot get into Dover Harbour if it is rough weather." He pointed

out that the object of the harbour was protection in rough weather. They said: "Never mind, you often cannot get into it if it is rough weather." It was supposed to do away with the silt, but opposite the Prince of Wales's Pier, you cannot moor vessels, as formerly." It was almost impossible for a man to say what the result would be of putting in any devices such as a harbour or a sea wall or a jetty. He was almost the first engineer to call attention to the topic of deep sea erosion, about which there were very different opinions amongst eminent engineers. On the Holderness Coast, in Yorkshire, there was a very large amount of stuff travelling all the way round in suspension. The cliffs between Flamborough Head and Spurn Point had been wasting about four feet a year for years. He had calculated how many hundreds of thousands of cubic yards must have been washed away and that stuff must go somewhere. Some of it went into the deep water, but the great portion was either laid along the bottom and travelled away, or was carried in suspension and deposited at different depths, from there, to be moved along and carried further down. The trend on the Holderness Coast was North and South, and he contended that the stuff was deposited across the mouth of the Humber, and, he believed, as far as the Wash. He had had experience on many coasts, and maintained that whenever there was a great erosion going on, and at the same time, an accretion or deposit of sand banks not far distant the probability was that the two were connected in some way, and how could they be connected except by the fact that what came from the one place went to the other? Skegness and the Wash were silting up very rapidly, and he assumed that the stuff that was taken from Holderness Coast, in Yorkshire, was carried to places where the accretion was observable. This was going on at the rate of about an inch every year, and two hundred years hence, or less, he believed that the Wash would be part of England, and 100,000 acres would be added to the area of this country. The Government should be asked to spend a little money in making sure of that. Many thousands of tons of coloured material, not indigenous to that coast at all, might be put down right into the sea along the coast. After a year or so, considerable portions of the sand on the shore at Skegness and the Wash should be microscopically examined, and the microscope would probably reveal the presence of this coloured material, and in that way give proof positive that the stuff was washed down. If it were not, the theory would be upset.

SIR GEORGE BUCHANAN, K.C.I.E., M.Inst.C.E., said that in Madras, which Professor Matthews had mentioned as a glaring instance of coast erosion, when there was a very bad storm the ships in the harbour at once weighed anchor

and went to sea, because the harbour was unsafe.

MR. W. WHITAKER, F.R.S., said they had heard of the difficulties which engineers had to deal with in contending against the inroads of the sea, and he could agree with the previous speakers in that matter, as he had seen how work at one place affected work at other places and caused damage. He had known cases where (say), £100 had been saved in one place, and damage to the extent of £1,000 had been caused in another. It was necessary to discover what was going on along the coast. It was a matter, not of isolated work, but of concerted work over a large area. It was often of no use that one individual or local authority should do work to protect itself, because the work must be extended far and wide. The southern end of Lowestoft was going rapidly as the result of what had been left undone by a neighbouring authority over which Lowestoft had no control. Lowestoft could do nothing to defend itself. The whole piece should be treated as one, regardless of who were the local authorities, and until concerted action of that kind was set up, nothing very great and important in regard to the matter of coast-defence would be done. There were places where it did not pay to defend the coast. There might be a long stretch of coast where the land was of little value, and it would cost a hundred times as much to save that coast as the freehold value of the land.

There was one thing that could be done at once, and that was that the taking away of shingle and sand on the sea shore should be generally prohibited. Nature had given a shingle defence, and that should not be allowed to be removed as a rule, because its removal was generally bound to result in damage elsewhere. He did not say there was no shingle in the world that could not be taken away without damage, and one instance was Dungeness, where the shingle extended a mile inland. It did not matter what was done with that; there was enough shingle there to satisfy the demands of the whole kingdom. On the shore nothing should be done, except where it could be shown to be harmless. In all such work, and in engineering works generally, nothing should be done to oppose nature, but rather to lead her.

MR. C. S. MEIK, M.Inst.C.E., said there was no branch of engineering that was open to more controversy than coast erosion. Engineers differed very seriously on all matters in connection with it. The drift of the East Coast was north to south, and on the South Coast from west to east, and it was agreed that the drift was with the flood tide. Those were the only two principles which were universally accepted with regard to coast erosion. Every district must be treated on its own merits,

and he did not think an engineer was fully qualified to deal with the case of coast erosion unless he was fully acquainted with the facts and knew the locality; he was simply wasting his client's money if he attempted work when he did not know the locality. Reference had been made to Lowestoft, and it was stated that the erosion to the southward was caused by the construction of a harbour there. The harbour was only constructed in 1835, and before that the coast line was unbroken, so that there was free travel for the shingle along that coast. There had always been a ness at Lowestoft, and that, at one time, extended for three-quarters of a mile from the base of the cliffs. Since the harbour was made, the ness had decreased, and erosion had gone on at a great rate, the high water line being now over one thousand feet further in shore than when the harbour was made. The erosion at Lowestoft had been going on for generations. Mr. Whitaker had referred to the travel of shingle, but what was to be done when the shingle went into the harbour at Lowestoft? It had to be dredged out of the harbour, and that was why the bulk of the shingle was taken away when it ought to go to the South. He agreed with all that had been said about the travelling of shingle on the East Coast. The larger material crossed harbour mouths or other obstructions, a great deal lodged in the Wash, and some of it went to form the sand banks of the coast. Undoubtedly the shoals in the Wash had been formed by material coming down the Yorkshire and Lincolnshire coasts. On the question of deep sea erosion, he did not believe anything such as had been described took place. He could not see how it could happen. The bed of the ocean had obtained equilibrium, and the Admiralty charts did not show any erosion.

THE CHAIRMAN asked how Mr. Meik accounted for the fact that there were five fathoms of water in places where it was once dry land. Up to a depth of 15 or 20 fathoms, there might be a certain amount of erosion.

MR. MEIK said the only other point he would refer to was the erosion on the Norfolk Coast. He thought that during the last year there had been more erosion than he had ever seen, and if any member of the Society wanted to spend a pleasant fortnight, he should walk along the coast of Norfolk. He would see erosion going on there at a tremendous rate, especially two or three miles north of Yarmouth. Within six months, as much as one hundred feet of coast had gone, and in one place, at Caistor, there was a hotel which was inside the sea wall, and was now on the verge of dissolution.

MAJOR ARTHUR J. MARTIN said there was great danger in putting up coast defence, if the work was afterwards neglected. He was

dealing, last summer, with a sea wall protection with groynes, which had sunk, with the result that there was a current undermining the wall. He expressed, on behalf of the audience generally, their indebtedness to Professor Matthews for his paper, and the wonderful series of pictures which he had thrown on the screen, and particularly the storm pictures. How they were got was simply a marvel. He had had the greatest difficulty in taking photographs of very small seas indeed, and the man who took the photographs at Hastings and elsewhere must have been a genius and something of a hero.

MR. C. H. COLSON, O.B.E., M.Inst.C.E. (Civil Engineer in Chief's Department, Admiralty), said that he considered that the formation of Chesil Beach was due to the joint action of the prevalent south-west winds which drifted the shingle to the eastward, and at the same time washed the finer portion of the shingle round the Bill of Portland into Weymouth Bay and the tidal currents setting up the Channel which split at the Bill of Portland, one section continuing up the Channel and the other being diverted in a North-western direction along the shore to Abbotsbury, which screened the shingle and washed its finer portions back towards the westward. Practically the same action was happening at every groyne and every headland up the coast. Professor Matthews had said that the littoral drift changed at Dungeness, and that this change was the reason for the formation of Dungeness. Mr Colson rather differed from him there. He knew the whole coast from Shoreham to Dover, and on that section the drift of the shingle over the whole length was from west to east, changing at Deal from south to north up to Ramsgate. Wherever a groyne or pier was put up on that section of the coast, it collected material coming from the westward, while to the east of such groyne or pier, finer material would be found coupled with an erosion of the coast line due to the fact that the groyne or pier had cut off the supply of shingle coming from the westward. For instance, at Hastings, the groynes were filled with shingle, while on their lee-side was sand. No doubt, at the bottom there was sand, and the heavier shingle was raised by the waves and thrown on the beach. For some reason or other, the supply of shingle over the whole coast line seemed to have been less in recent years, and the fact that so many people were now erecting groynes tended to restrict the movement of the shingle to a much greater extent than had obtained in the past. At Kingsdown, for instance, within his knowledge, the shingle had been cleared away from Hope Point as far as the butts of the Admiralty Rifle Range almost entirely, while between the butts and Kingsdown large portions of the shingle had been removed, and it appeared that in a comparatively small number of years, unless

something very drastic was done, the houses which now stood on the beach at Kingsdown would have their foundations washed away. Unless there was a sufficient supply of shingle being washed along the shore to fill them, it was no use constructing groynes. Mr. Colson wished to draw attention to an interesting physical characteristic near Sandwich. At the present time, the River Stour ran between the Isle of Thanet and the mainland close to the Thanet shore to within a short distance of Ramsgate, where it turned and ran towards Sandwich. At Sandwich, the river turned back on its course and eventually discharged close to Pegwell Bay. The turn of the river to the south seemed to have been caused by the bank of heavy shingle coming from the north which forced the river back to Sandwich. Then for some reason the flow of shingle ceased from the north, and the drift coming up from the south forced the river right back to its original outlet near Pegwell. The shingle which came from the north contained a large proportion of large stones which had apparently travelled only a short distance, and presumably had come from the Ramsgate cliffs. The whole instance was interesting as showing a definite change in the drift of shingle. Another instance of a river being turned in its course by shingle was that of Shoreham, where the shingle coming from the west had gradually forced the River Adur far to the eastward and had blocked the town of Shoreham from the immediate access to the sea, which it enjoyed in Roman times. With regard to the Chairman's remarks on Dover Harbour, he happened to know the harbour well, and did not think that the remarks which the Chairman had made were quite just. Dover Harbour could be entered by the eastern entrance in any state of the weather.

THE CHAIRMAN said he was only relating what a skipper told him, who said it was not possible to get into Dover Harbour in stormy weather.

* MR. COLSON said that he thought it was possible to get into Dover Harbour by the eastern entrance in any weather, although owing to the position of the western entrance access by that entrance during a south-western gale was not so easy. As regards the silting being abnormal, he could only say in justice to Sir William Matthews, Past President, Inst.C.E., who designed the harbour, that the silting which had actually occurred was just what Sir William had predicted in his report on the conditions before the harbour was constructed. No doubt, at the present time, there was an accumulation of silt in the harbour because it had not been dredged for some years. With regard to the statement that the Prince of Wales's Pier had silted up—while no doubt a certain amount of silt had accumulated on the western side of the pier, on the eastern side there was deep water, and this deep water had, in fact,

been increased during the war owing to the alteration in the currents in the harbour which had been caused by the position in which certain ships had been sunk during the war to protect the harbour against torpedo attacks.

CAPTAIN I. J. GRAY said he had been engaged wholly on sea defence work for a number of years, and since then he had made it his business to keep himself acquainted with the progress made in that branch of engineering. In every sea defence problem one had to study a number of phenomena, marine, metallurgical and geological, and, besides that, collect old and new data. The data which one obtained were not altogether satisfactory, and if they were they would not be conclusive, like mathematical facts leading to a solution. What they arrived at was a general result. General inferences were a complex made up of applied science and experience, but experience played by far the larger part in ocean defence. Unless the sea defence engineer had had a long and varied experience—an experience such as the author had had—he would find himself up against a problem the individuality of which would jeopardise the soundness of his conclusions. He submitted that it was not only desirable, but often necessary, and it was undoubtedly possible, to raise the level of sea defence work so that it partook more of the nature of an applied science than it had hitherto done. Scientists had discussed tides and waves in mathematical terms, and there remained a large number of phenomena which might be scientifically investigated. There was a wide field of research in which scientists and engineers might co-operate, but it was not the work of individual effort, and he suggested that a Committee representative of engineers interested in tidal matters, should draw up a syllabus of problems in which research was required. He would make no attempt to indicate them himself, but he had no doubt that amongst those present such a syllabus of problems could be mentioned quite easily. Engineering societies had not done what was wanted. Papers were read describing successes, but one never heard a paper on sea defence describing a failure, and failures were not infrequent. Every equinox told the tale, and if there was no society dealing with sea defence on scientific lines, he saw no alternative except waiting until there was a Government which would act generously on the lines of the Commission on Sea Defence which was appointed some years ago. In the existing circumstances of national finance, he was afraid that it could not be discussed.

THE CHAIRMAN proposed a vote of thanks to Professor Matthews for his paper. He himself had been engaged, and employed in many shore service matters, and the removal of shingle

was the one great trouble. He could specially call to mind one case which occurred in the locality of Dublin. A certain portion of the coast had a railway line, the South Eastern line, which ran close to the shore over the top of the 20 feet sea wall. There was a lot of very heavy shingle there, and very little sand on the shore at all. A certain man made a practice of taking hundreds of tons of that, and got a large sum by selling it. He interviewed the railway company, and found that the man had a perfect right to take the whole of the shingle because it belonged to him, but on the other hand, he was jeopardising the existence of the railway line, and so the case came into Court. He was giving expert evidence, to the railway company, and was cross-examined by one of the leading lights of the Irish Bar, Mr. Stephen Ronan, K.C., who said: "Are you quite sure that the sea wall protection is formed by the shingle that my client is taking, and was it there before my client was taking it?" He answered that it was a conditional question. Mr. Ronan said he wanted an answer, "Yes" or "No." He appealed to the Judge to allow him to ask Mr. Ronan a question in order to put his point; the Judge gave permission, and he then asked Mr. Ronan: "Have you given up assaulting the police?" Of course he did not know what to say, because if he had said "Yes" it would mean that he had been in the habit of assaulting the police, and if he said "No," it meant that he was still in the habit of assaulting the police.

The motion was seconded and carried unanimously.

PROFESSOR MATTHEWS, in response, said it was extremely gratifying to him that the paper had been so well received. Coast erosion was probably the greatest difficulty that any engineer had to contend with, and there was no branch of the engineering profession that was so discouraging as that of the maritime engineer, who specialised in coast protection. At Bexhill there were broken pieces of a sea defence on the shore, and the remains of a still previous wall. Instances like that could be found all round our coasts, and there was nothing more discouraging, and that was chiefly due to the fact that correct data could not always be obtained to guide an engineer in designing coast protection works. The conditions on the East Coast, e.g., were totally different from those on the West and South Coasts. He quite agreed with what had been said with regard to the drift at Holderness, and in his opinion the accumulations that were taking place in the Humber and the Wash, had come directly from the Holderness Coast of Yorkshire. They could all learn a good deal from failures, and when he was called in to advise a local authority, he always made the fullest enquiries

from sea-faring men who knew the coast and the tide. Much valuable information could be obtained in this way. Lord Headley had referred to deep-sea erosion, and it would be interesting to the audience to know that the Chairman was one of the first who drew attention to this. Some years ago Lord Headley (when Mr Allanson-Winn) designed a chain cable groyne, which was carried out some distance below L.W.O.S.T., and to which were attached faggots. This groyne was quite satisfactory, but the difficulty was in getting the attachments to adhere to the cable. During storms, they soon washed away, but with reasonable attention, they did useful work in preventing drift of material along the shore below L.W.M.

The proceedings then terminated.

DR. JOHN S. OWENS writes:—

I propose to refer to one point only in Professor Matthews' paper, that is, the wearing, or attrition, of concrete surfaces exposed to sea action. All engineers who have had occasion to observe works of concrete upon the foreshore where they are exposed to the action of coarse shingle have observed the rapid wear which often occurs. In the case of walls or groynes constructed by me upon the South Coast, where very coarse flint shingle is abundant, I have tried several methods to minimise this attrition. Wall faces were initially made from pre-cast blocks formed from elvan granite, as being the toughest obtainable stone. The face thus obtained was fairly resistant to attrition, but in course of time it wore away.

Since then walls have been faced with large flints, over about 4 inches diameter, set in concrete, and these have also stood fairly well, but I do not think they have withstood attrition appreciably better than the concrete blocks. I find that the peculiar property which the flints possess of fracturing easily under a sharp blow was most objectionable, and the surface of all flints exposed broke down by intersecting conical fractures, and gradually wore away.

On considering the causes leading to wear of concrete it appeared clear that if the pressure due to the impact of the stones against the face could be reduced it would help matters. A stone travelling at a high velocity under the influence of wave action, if suddenly checked by meeting a hard surface, will exert a pressure inversely proportional to the elastic depression of the surface, that is if the stone is brought up by striking a surface which depresses, say $1/100''$, the pressure of the blow will be ten times as great as if the surface depressed $1/10''$.

I, therefore, tried to obtain a resilient surface by coating the concrete with compositions of tar, pitch, etc., but these did not prove durable, and ultimately an experiment was made with wood block facing similar to a road pavement, the blocks being set with end grain on the surface. With due precautions to avoid ex-

pansion after setting, this wood block facing has stood the test of attrition better than any other surface.

One patch of such facing has been in existence for something over a year without any ill-effects, and a second patch which has been in for about four months shows very instructive results. A recent inspection of the second patch, which was exposed to great attrition by flint boulders, showed that the face of the blocks had suffered no observable wear, while the flint faced concrete surrounding the blocks, in which they were set, had been worn back below the face of the blocks by about $\frac{1}{4}''$.

It is perhaps too soon to say that this is a solution of the problem of attrition, but I feel very hopeful. It is not to be expected that any material will stand indefinitely when exposed to the grinding action of stones driven by the waves, but a material such as the wood block facing which resists attrition by virtue of the softening of the blow and of its own tough nature is very promising, especially as such a facing can be easily repaired if injured.

MR. C. S. MEIK writes:—

With reference to Mr. Colson's remark on the shingle outside Sandwich harbour, I am of opinion that the accumulation is due to the south-west sea running up channel; any sand in the bay being brought in by the sea under the action of north-easterly winds. Some few years ago I happened to be at Deal, and noticed the shingle had been scoured away, and the foreshore depressed to the extent of several feet during a northeasterly gale: two days afterwards, when the wind had gone round to the south-west, the whole of the shingle was replaced on the beach. This happened between Sandown Castle and the entrance to Sandwich Haven.

PROF. HENRY ADAMS, M.Inst.C.E., writes:—

This very interesting paper presents a summary of all that is known upon the subject. The author shows very clearly that there is no standard design possible for protecting our coasts but that every case must be decided according to its circumstances. The Chesil bank and the action of the sea round Portland are a source of never-failing wonder and mystery. A very similar bank at Westward Ho is not referred to, but the same action has taken place there; a long ridge of cobblers' lap stones rises at the head of a wide sandy beach, with no indication of where they came from.

As to the travel of stones varying with the size, it should be noted that the bulk and, therefore, the resistance, varies with the cube of the mean dimension, while the area receiving impulse from the waves varies only with the square of the mean dimension; one would, therefore presume that the smaller stones would travel furthest. On the other hand the slope of a beach varies with the size of the particles,

shingle being steeper than sand in the proportion of its size. Where the beach is mixed the shingle generally takes the higher position and the sand the lower position. This would seem to be direct evidence that the larger material travels furthest.

The cooling of the earth during geological ages must of necessity have caused a shrinking and consequently a crumpling of the crust which is the cause of the mountain ranges and sea valleys. There have been continuous changes in the level of the land from this cause, and it is well known that similar changes are still in progress. One can hardly understand Mr. Clement Reid's opinion that "The rise of the sea level (i.e., the subsidence of the land) may have been completed about 3,500 years ago, and only then commenced the coast erosion which we now see." There is no doubt that coast erosion is and has been continually in progress, more or less throughout the world, and that the tendency is to raise the bed of the oceans and seas and therefore to that extent raise the mean tide level. Where the erosion is greatest the travel along the coast will tend to increase the deposit at points where obstructions occur, but this will not alter the fact that much material is carried into the sea itself. The gradual rise of the mean tide level at Liverpool may, however, be due to the sinking of the land, but this could be determined by taking levels through from some distant point and checking by the Ordnance Survey. Buried forests at various points round the coast are direct evidence of the sinking of the land, but, as already shown, the land is constantly altering its level owing to the shrinkage of the earth's crust.

Reinforced concrete is a most valuable material for all sea-coast works. The ability to make a tied structure of any extent, with a face that gives little friction and can be shaped as desired, leads one to doubt whether anything better can be conceived. A few cases have been found, where from previous concrete or other cause some corrosion of the steel reinforcement has been caused by the sea water, but the use of rustless chrome steel would entirely prevent this possibility.

The writer's idea of coast protection is to prevent the travel of beach material along the coast by suitable reinforced concrete groynes, to protect the base of the cliffs by reinforced concrete walls, and to provide for the proper drainage of the adjacent land. The starving of the coast on the leeward side of the groynes, which is often objected to, is simply explained by the groynes not being continued sufficiently far along the coast, and that concerted action is necessary to prevent any one place benefiting at the expense of its neighbour. So long as the Government contend that coast protection is a local and not a national matter, so long shall we have periodical outbursts of indignation

at the ineffective action taken to preserve our coasts.

MR. A. E. CAREY, M.Inst.C.E., writes :—

Professor Matthews' paper affords a useful summary of recorded data bearing on the subject of Coast Erosion. He does not directly indicate the State measures which he considers essential to the solution of the problem.

In Appendix No. XVII. of the report of the Royal Commission, I elaborated a "Memorandum with regard to the Proposed Creation of Coast Commissioners," and in Chapter 13 of "Tidal Lands," the authors have dealt with this subject somewhat fully, sketching in outline a draft of the Act of Parliament which, in their judgment, would meet the case. It is safe to say that if, to-morrow, a benevolent despot could be appointed, whose function it should be to control the problem of erosion, that problem would speedily cease to be acute. The inherent difficulties of the situation arise from the vast complexity of authorities and their lack of united action, coupled with the difficulty of finance.

It is quite certain that the benevolent despot, when installed in office, would call to his aid the services of the horticulturist. The lack of interest shewn in the comparatively simple operation of transforming our foreshores by the agency of vegetation is somewhat amazing in a country in which horticulture in all its branches is a passion with almost every class. The authors of "Tidal Lands" ventured to suggest that sea-side gardening might some day become a recognised branch of horticulture, but, so far as I am aware, with the exception of the protection of the cliffs at Bournemouth by the growth of succulents, which had been so successfully inaugurated by Mr. Dolamore, the Borough Engineer, there is little trace of any attempt at this novel art. Mr. Dolamore has planted the Giant Mesembryanthemum (*Cereus rosea*) on the cliffs, having found it indigenous in Cornwall and Devon. He has clothed some of the slopes with both the yellow and blue varieties.

The horticulturist who has to deal with the difficulties of shingle protection would undoubtedly call to his aid the plantation of *Sueda fruticosa*, one of the most useful of allies.

Mr. Chilvers, of Hunstanton, has been growing *Sueda* freely for the purposes of coast protection, but, so far as I know, his efforts in that direction have not met with the success they deserve.

In recent years my firm have had, in a number of instances, to advise on coast erosion, and have also been responsible for the wardenship of considerable tracts of sea walling. In every case the endeavour has been made to carry out the necessary measures with the minimum of expenditure. There are large areas of the sea shore in process of erosion or falling into dis-

service by reason of the encroachment of the sea, which, in my opinion, could be maintained in being at relatively small expenditure. The view prevalent a few years back was that, considering the stupendous forces at work upon sea shores, vast and elaborate measures of defence were necessary. The modern school has, perhaps, gone to the other extreme. It regards non-heroic methods of shore and cliff plantation and arrest as the key to the solution of the problem.

MR. SAMUEL DYER, M.I.MUNL.E. (Bridlington) writes:—During the years when Mr. Matthews was our Borough Engineer and Surveyor, he had unique opportunities of watching the action of the sea, and devoted much time and thought to the subject, and shewed great ability in designing and carrying out works of prevention. Unfortunately, this is a district in which the sea has made terrible inroads upon the land; whole villages have been swept away and a bay formed from Flamborough Head to Kilnsea, a bee line of 35 or 36 miles, and having a depth of 7 miles.

MR R. F. GRANTHAM, M.Inst.C.E., writes:—

I should like to point out that while erosion of cliffs by the sea causes loss of land over a much greater length than any other kind of encroachment, the sea advances on the land in a different way where low land is protected only by the high ridges of shingle banks and by sand dunes, and protection of those low-lying lands is more difficult than that of land on cliffs.

In the case of high shingle banks, the sea in violent storms throws the high ridge back and deposits the shingle at the back in long talus fans of flat slopes, thus gradually encroaching on the low land. This was happening at Lancing and Shoreham until groyning work stopped it. It is happening now on the marshes in rear of the long ridge of shingle bank mentioned by the author on the Norfolk Coast, extending from Weybourne, which I have recently had occasion to inspect.

In some parts where the coast is protected by the sand dunes, the encroachment of the sea is almost imperceptible, but it is, nevertheless, in progress. The tides fret away a small portion of the foot of the dunes and the front slopes then fall down and the sea advances while the sand dunes recede. I have seen this in progress on the east coast of Norfolk.

I did not think that any engineer would dispute, as the author appears to question, the accuracy of the conclusions arrived at by the late Sir John Coode from his extended and most careful observations of the movement of the shingle on the Chesil beach as described before the Institution of Civil Engineers in 1853. I have seen over and over again after violent storms on the south coast the largest stones on the shore, mostly chalk flints, thrown up to

the top of the beach on the west sides of the groynes, while the smaller stones are left lower down. This fact, as it seems to me, fully confirms Sir John Coode's conclusions on the subject. I do not see how indentations on the Dorset coast, as the author suggests, can affect the movement of the shingle on the straight run of 10 miles of the Chesil beach.

The author is under a misapprehension when he states with reference to Shoreham Harbour "since the pier was extended it has been impossible for any of the material to travel eastwards." The west pier was extended about 150 feet in about the year 1879 by Mr. (afterwards Sir) Alexander Meadow Rendel. I have recently prepared plans for the repair of part of the extension. I have also been engaged for many years on works on the coast between Worthing and Shoreham Harbour on the west side of the pier and have had occasion within the last two years to inspect for some months and report upon the conditions of the beach and groynes on the east side of the pier. I am, therefore, fairly well acquainted with the movement of the drift of the coast.

So far from it being impossible for material to drift eastwards of the pier, I can assure the author that very large quantities enter the harbour and also pass the pier and are deposited all along the beach on the east side of it. The Harbour Trustees have since the pier was extended been compelled to dredge from 60,000 to 120,000 tons of shingle annually from the harbour to keep it clear. I have also seen large banks of shingle deposited by the tide on the east side of the pier, the shingle from them being gradually washed up on the beach eastwards. The pier does not stop the movement of shingle eastwards at all. If it did the large quantities of shingle now to be seen on the beaches at Hove and Brighton could not be maintained.

Harbour piers, as a rule, do not ultimately intercept the passage of all drift material. The conditions at Madras Harbour, which the author quotes, are a striking example of the difficulty of stopping the drift material and of keeping harbours clear of it.

The author refers to Dungeness, quoting from the late Mr. W. H. Wheeler's book "Sea Coast."

I have never been able to accept Mr. Wheeler's statement that the only source of supply of shingle forming the immense bank of the area of Dungeness is derived from cliffs between Dungeness and Beachy Head. So far as I have been able to investigate the question, those cliffs could not have yielded the enormous quantities deposited there. A great deal of the shingle must have travelled a long way from the west. The Rev. F. Gell, formerly Vicar of Lydd, sent in 1895 to the British Association Committee on the Erosion of the Sea Coasts a list of various pebbles found at Dungeness. Among them were quartzite, similar to pebbles

from Budleigh Salterton, Porphyritic felsite-quartz porphyry, possibly Cornish elvans, granite and hornblende porphyry. These are not products from the Hastings and Beachy Head cliffs. I have myself picked up Budleigh-Salterton pebbles on the shore west of Littlehampton and on the shore east of Chichester Harbour.

"Deep sea erosion" is a term which has frequently been used in connection with erosion of the coast. I should be glad if the author could explain what in this connection "deep sea" means—that is to say, in figures of depth. I have seen quantities of chalk flint with seaweed attachments thrown upon the shore after violent storms, but they could not have come from a greater depth than a fathom or two. Investigations have been made of the conditions of life at great depths in the ocean where the deep sea is reckoned by hundreds of fathoms. It seems likely to lead to misconception to apply the term "deep sea" to comparatively shallow depths of water. The cavities left by the stones with seaweed attachments are soon filled with sand or shingle. According to the late Mr. John Murray, who read a paper on "The North Sea" before the Institution of Civil Engineers in 1861, that sea is gradually shoaling, and it is nowhere deeper than 100 fathoms, except on the margin of the Norwegian coast.

I agree with the author that groynes are necessary for the protection of most sea walls. But I have found it quite practicable in several cases to stop the erosion of cliffs by means of groynes without any sea wall or breast-work of any kind, although the process is rather slow.

The author refers to the large reclamation scheme for enclosing 150,000 acres in the Wash in about the year 1840. This area was subsequently reduced to 75,000 acres and again to 32,000 acres. If such a scheme had been carried out it would have enclosed an area utterly unfit for reclamation and absolutely useless for any purpose whatsoever. An embankment was started and small remains of it are still to be seen. The result of the Estuary Company's operations has been to reclaim about 2,400 acres in a period of over 60 years. The Company, however, has judiciously enclosed by degrees only land which was really fit for agricultural purposes.

One other point which I think requires qualification. According to my experience marsh land is much more valuable than cliff land.

An owner of marsh land fronting the North Sea informed me within the last three weeks that he let his marshes for £2 10s. to £3 per acre. Marshes in Essex and in Lincolnshire have frequently been let by auction for at least £4 per acre for pasture. Where is the agricultural land on wasting cliffs that produces equal values or anything like them?

MR. A. T. WALMISLEY, M.Inst. C.E., Dover Harbour, writes:—

I agree with the statement that "the larger materials," are forced against the base of a cliff, leaving the sand to settle near low water, as the larger material, unless too heavy to be pushed forward by the travel resulting from the action of waves, presents a surface for the force of water to act upon, which the small particles of sand cannot claim. There is in such circumstances a wave of oscillation acted upon by the prevailing wind, which becomes a wave of translation when a solid obstruction to its revolution is encountered, and this translation upon a beach foreshore is resisted by properly constructed groynes, carried well into low water, so that the foreshore elements are not conveyed round the toe of the groyne, and the construction should also be carried up to a sea wall or slope above the level of high water. I have no sympathy with short groynes, the length of which does not include the position of high and low water levels, and I cannot favour cutting a hole in a groyne to allow shingle to travel through a groyne, when the beach upon the lee side is much below the beach upon the windward side of the groyne. This has been done at some seaside places, about the level of high water, neap tide, but so far as I know, this plan has never given satisfaction, as it produces scour. The groynes are best constructed when the verticals of a timber construction allow the top level of the groyne to be raised or lowered, to suit accumulations of beach. Old railway rails, pointed and driven vertically, form excellent supports for this purpose, but need cautionary methods when small boats have to pass over the site between high and low water levels.

Under "Causes of Coast Erosion," the author alludes to Lowestoft, where an unstable wall upon the south beach facing the sea was built by contractors to retain the ground behind the wall, and they were told that in doing so, they must not take the beach for concrete. Consequently when the surface of the beach in front of the wall covering its toe receded, the wall was subject to undermining, owing to the insufficient groyning at that time (1892), but the contractors argued that as it was specified that the beach was not to be interfered with, they were justified in concluding that the groyne would receive sufficient attention to retain the beach, and the wall was not designed to stand without the aid of the beach to protect its footings. The range of tide here is 6' 6". Of course, under the circumstances, the base of the wall should have received the aid of piles, cylinders or caissons, to obtain a sure foundation. Where there is ample width of foreshore to construct a marine drive or parade in front of the face of a cliff, at the back of a sea wall, this plan forms a protection to the cliff, as the water which breaks upon the wall, and falls

upon the parade, can be drained off the surface of the walk, as at Westgate-on-Sea, Folkestone and other places, without attacking the cliffs.

As regards a sea wall bounding the upper portion of a foreshore, Mr. Walmisley prefers a vertical wall. A curved faced wall does not tend to contribute more beach than a vertical wall, and the toe of a curved face wall being part of an inverted arch, is not so stable as the base of a vertical wall. A curved faced wall may also need the introduction of a projecting cornice (as pointed out by the author), to divert the water from leaping the wall and falling to some extent upon the retained road or promenade at the back, and if inserted below the coping, will tend to raise it out of level, whereas projecting offsets to the face of the wall where their bed is embedded in the structure, so that the water cannot press underneath this projection are beneficial, as in stormy weather they would protect the main foundation from the detrimental action of falling water. Such projections were formed of 9 ins in 6 to 1 concrete blocks, 6' 6" by 3' 0" depth in the retaining wall, faced with flints, at the west end of the parade at Sandgate, near Hythe, and were carried down to a clay level, but probably not sufficiently encased therein, so that the wall failed owing to the pressure of the high ground at the back of the wall, when aided by the recession of beach on the foreshore. Settlement resulted in most of the houses upon the land side of the carriage road, and a gas service underneath the inside footpath had to be ignited, to exhaust its supply from broken pipes beneath the asphalt surface.

The whole subject of Coast defence is of national importance, but it will be readily conceded that whatever is done in such matters, needs watching with a view to maintenance, whereby the demand for heavy future expenditure may be avoided.

MR. F. J. WARING, C.M.G., M.Inst.C.E., writes :—

I agree generally as to the causes leading to erosion, as given in the paper, but think it difficult sometimes to account for this taking place at one spot, while at another, close by, accretion is apparently in progress. Thus, in Eastbourne, groynes are in existence along the sea front to check the travel of the shingle which, if unchecked, would probably result in erosion, while to the east of that town there are no groynes, but accretion is taking place, and that accretion must have been in progress for centuries, as, at a point distant about $1\frac{1}{2}$ miles from the Coastguard Station at the east of the town, the shingle extends inland to the Pevensey Road, which there is approximately a mile from the present shore line.

As regards the best means to be taken to prevent or check erosion, it is almost impossible to lay down any general rule as this should be determined by the local conditions applicable

to each particular case. I might mention that on the west coast of Ceylon, where the range of tide is only some two feet, and the seas are not nearly so heavy as those met with at many parts of the coasts of the British Isles, the sandy foreshore is being eroded, thus endangering the railway which at the place runs at the extreme edge of the shore. The Colonial authorities proposed, as a remedy, the erection of a sea wall founded on concrete cylinders. Upon the matter being referred to my late firm, the opinion was given that the erection of this wall was unadvisable, as the recoil of the waves from its face would intensify the erosion and ultimately entail the need for protecting the wall itself by a rubble facing or otherwise. There being abundance of gneiss rock available within a reasonable distance, the formation of a rough rubble facing laid to a fairly flat slope was recommended, the stones in the face exposed to the sea to weigh from 3 to 9 tons, any smaller material quarried being used in the hearting and backing. The work was carried out in this manner for a distance of some $2\frac{1}{2}$ miles, at a cost of rather more than one-fifth of the estimated cost of the sea wall, and it was finished at the end of 1913. The result has been quite satisfactory, and though, as was foreseen, some little settlement into the sandy shore on which it was founded has occurred, the cost of its maintenance has been but small.

MR. ERNEST LATHAM, M.Inst.C.E., writes :—

If there is any criticism which can usefully be made, it would be a regret on my part that the "prevention" side of the paper is not further elaborated. With nearly all the views expressed by Professor Matthews, I am in agreement. The following remarks, therefore, are principally confined to those points on which Professor Matthews and I are not in absolute accord :—

Professor Matthews states that "Rows of piles have sometimes been driven parallel with the shore, and a few feet seawards of the cliffs or sea wall, but these have been quite unsuccessful."

This is a generalisation which is not always correct. My firm (Messrs. Carey & Latham) recently advised the Somerset County Council in regard to the protection of the Minehead-Watchet road. A leading feature of the design was a double system of open piled stockades on the foreshore and running parallel with the lateral defences. Acting under this advice, the County Council have spent over £30,000. The prevalent wind on this coast is from the West and North-West, and the stockades are successfully collecting the beach material in front of the sea wall. The beach consists of shingle graded up from the fine particles to 6in. material. Some interesting photographs of this work appeared in the "British Builder,"

dated February, 1922. I agree in general with Professor Matthews' conclusions as to groynes and the provision of an adjustable crest near high water mark, although he belongs to that school of engineers who admittedly avoid the construction of groynes and only adopt them as a last resource.

During the construction of the works above referred to, and before completion, a bad wash-out occurred, and the last resource was adopted in modified form. This modified form involved a groyne of low elevation and a wide base, 18 feet in the case under review. The groynes were of mass concrete about 4 ft 6in. high and only extended some 20 ft. seawards of high water mark. The section of groyne was given an easy gradient on both sides, and these groynes functioned as a sort of non-return weir over which the beach material was driven by the prevailing winds and the influence of the flood tide. The beach loss under adverse winds being less than the gain under favourable winds, a steady accretion has occurred along the toe of the bullnosed sea wall now carrying the county road.

It is undoubtedly a source of regret that national economies have resulted in the disappearance of the Lands Reclamation Department of the Ministry of Agriculture and it certainly appears as though the problem of coast erosion will continue to remain, as hitherto, a local and not a national problem.

It will interest Professor Matthews to know that I reported to the War Office in 1914, in connection with the Orfordness Peninsula. The rivers Alde and Ore are identical, and the menace of a severance of this Peninsula at the hamlet of Slaughden is as serious as ever.

In reply to the foregoing communications, PROFESSOR MATTHEWS writes:—

In reply to Mr. Ernest Latham, I stated that in my opinion rows of piles driven parallel with the shore were almost always unsuccessful, certainly 9 times out of 10; I am pleased to know that the work recently carried out by Messrs. Carey and Latham, in Somerset, has proved so successful. I have seen the article which appeared recently in the "British Builder," and noted with much interest this novel form of construction.

I was pleased to note that Prof. Adams' experience has shown him that, generally speaking, smaller stones on a shore travel furthest. I agree that reinforced concrete is one of the most valuable materials for all sea-coast works, and while occasionally examples of failure have been found, it is usually due to defective work. I do not agree with Prof. Adams that by extending the groynes on a shore erosion would be prevented. I am strongly of opinion that concerted action to prevent erosion is necessary.

I agree with Mr. Carey that it is difficult

to formulate any entirely new points in connection with coast erosion and protection. It is also difficult to say what the State should do in the solving of this problem, but it is certainly disappointing to find that the "Lands Reclamation Department of the Ministry of Agriculture" has now been dispensed with.

The communication sent in by Mr. S. Dyer, of Bridlington, is interesting in that it points out that the greatest erosion occurring around our coasts is on the Holderness Coast of Yorkshire, where I resided for some years and made a careful study of the tides, and wave-action, and erosion.

Mr. Grantham's remarks are interesting and important. I agree that it is more difficult to protect low-lying land (say marsh land) than to prevent erosion of cliffs. I agree with Mr. Grantham that even where sand dunes protect a coast encroachment by the sea is often in progress, although it is imperceptible. In regard to Mr. Grantham's reference to the most careful observations of the movement of the shingle on the Chesil beach, no one appreciates the splendid work in this direction, performed by the late Sir John Coode, more than myself, and I would not think of setting my opinion against that of Sir John; but I have observed on various parts of our coasts that the smaller material travels farthest; in the case of the Chesil bank (according to Sir John) the reverse is the case.

With regard to Shoreham Harbour, probably I was not quite accurate in saying that it was impossible for *any* of the material to travel eastwards. Mr. Grantham would probably admit that very little material does travel eastward, and the quantity which accumulates in the harbour mouth cannot be said to travel eastwards. It would be interesting to know what becomes of the 60,000 to 120,000 tons of shingle annually removed from the harbour.

As to Dungeness I am inclined to agree with Mr. Grantham that the cliffs at Hastings have not in themselves supplied the whole of the material that we find at Dungeness, but that some of this has travelled from parts of the coast much further westward than Hastings.

Regarding "deep-sea erosion," by this I mean erosion considerably below low-water mark (spring tides) and anything up to say 7 fathoms deep. I am pleased to know that Mr. Grantham has found it possible in several cases to stop the erosion of cliffs by means of groynes only without any sea wall or breastwork of any kind. I have, unfortunately, not been so successful.

I am glad that Mr. Walmisley agrees that it is wise to carry groynes down to low water mark so that material will not escape around the toe of the groyne, and that he has no sympathy with short groynes.

As to the suggested opening through the upper portion of a groyne (at the shore end)

I would say that I have not introduced this method, but that I have seen it adopted at Clacton, and upon enquiry was informed that the method worked well. Mr. Walmisley's reference to certain unstable walls upon the south beach at Lowestoft, shows clearly that the best workmanship should be put in in the carrying out of coast protection works. I have seen these defective walls and agree that whatever works are carried out should be substantial having in mind the cost of maintenance.

The communication sent in by Dr. John S. Owens is particularly interesting as it deals, among other matters, with the wearing action of concrete blocks or mass concrete sea walls faced with flints, and it is useful to know that he has come to the conclusion that concrete blocks faced with flints, which form the face of a sea wall, withstand attrition (caused by the sharp flints on the shore being hurled at the wall in a heavy storm) no better than plain concrete blocks. His investigations are very interesting. I, however, do not agree with Dr. Owens' novel method of facing a sea wall with wood blocks; there must in my opinion be an expansion and contraction of the blocks according to the temperature and a splitting of the blocks as one finds often in wood block paving on the road.

I am indebted to Dr. Owens for the use of a number of interesting slides illustrating groynes and sea walls, designed and constructed by him.

In reply to the written remarks of Mr. F. J. Waring, I agree that there is a good deal of difference of opinion as to the causes of coast erosion, but I believe that the causes set out in the paper are the principal ones. I have often observed that alarming erosion and considerable accretion are in progress together on quite a short length of coast. The Eastbourne example referred to by Mr. Waring is particularly interesting. There is no general rule that can be laid down when designing a scheme for coast protection: local conditions affect the scheme considerably.

NOTES ON BOOKS.

THE MINERAL RESOURCES OF BURMA. By N. M. Penzer, M.A., F.R.G.S., F.G.S. London: George Routledge & Sons, Ltd.; New York E. P. Dutton & Co.

The Federation of British Industries, under whose auspices this book is published, has done well in calling attention to the mineral resources of Burma. The potential wealth of the country is very great, but at present its development is rendered almost impossible by the lack of adequate means of communication. If this could be remedied, there is little doubt that a swift and enormous development of the mineral resources of the country would follow, with the result that our industries would be enabled to obtain large quantities of raw materials from

within the Empire, and, at the same time, a demand would be created for machinery and many other kinds of goods, the bulk of which would naturally be supplied by this country.

Mr. Penzer's volume is to be commended as giving in a handy form a comprehensive account of the minerals of Burma. After an introductory chapter describing generally the climate, physical features and roads and railways of the country, the author proceeds to deal with the minerals *seriatim*. Gems and precious stones are first discussed. The average annual output of rubies, sapphires and spinels during the five years 1909-13 was 283,439 carats, valued at £63,272, and the industry employs some 1,300 to 1,500 men. Jade is a mineral of some commercial importance. The jade mines in the Kachin Hills are only worked for three months in the year, and the methods are primitive. During the heavy rains, all work is stopped by malaria, and before mining is re-started, it is necessary to bale out the water which has collected, and to renew timber which has fallen in or rotted. The output for 1918-19 was 3,336 cwt., valued at £91,456. With more scientific methods of production, these figures could, no doubt, be multiplied many times.

Some interesting particulars are given showing the increase in the production of tin. In 1898 this amounted to only 39 tons, valued at £2,553; by 1913 it had risen to 353 tons valued at £47,384. During the war years 1914-18, the average production of tin and tin ore in the Indian Empire, was 11,981.7 cwt., valued at £73,376.

The extraordinarily rapid growth in the petroleum industry is due mainly to the Burma Oil Company. Their first bore was sunk in 1887 in Khodaung. In 1900, the production from machine bores was 19,030,196 gallons. In 1919, the total number of gallons from the Burma oil fields reached the great figure 293,748,807.

An interesting feature of the book is a map of Burma showing at a glance the districts in which the various minerals are found; and the volume concludes with a full bibliography which will be very valuable to those who desire to study the subject in greater detail.

PUNJAB CEMENT INDUSTRY.

To travellers, whether by road or rail between Pindi and Peshawar, the grey hill and shrine of Baba Wali Kandahari, rising abruptly from the plain above the village of Hasan Abdal, are well-known features of the landscape. Beneath its western slopes lie the sylvan groves sacred to the memory of Lala Rookh, fickle slave mistress of Jehangir. Her tragic end no less than the legend of her illicit love has carried her name down to posterity and her tears, so the story goes, still flow perennially from beneath her living tomb. To the south-east rise the turrets of the ancient house of Wab,

a halting place of Mogul emperors on their excursions to and from Kashmir, the gateway of whose garden palace still stands among the ruins of a greater splendour. A change has come over the scene in the last few years, which bids fair to bring the name of Wah out of its slumbers into the forefront of utilitarian fame.

It has been said that the measure of a country's prosperity may be gauged in these days of industrial progress by the extent of its cement interest. Whether or not this is true, it is a fact that without cheap and plentiful supplies of Portland cement the progress of industrial development is greatly hindered and that the recent industrial awakening of India generally has synchronised with the development of the manufacture of Portland cement in various parts of the country, so far mainly in the centre of the Peninsula and on the west coast.

Now, as recently forecasted by H.E. the Governor, the Punjab, not to be behind the rest of India in industrial advance, is to possess a cement factory of its own and the site selected is to the east of the hill of Baba Wali Kandahari, giving it a new and wider interest than it has hitherto held.

The site which was selected by the promoters, Messrs. Killick Nixon & Co., of Bombay, after an exhaustive examination of the possibilities of many other areas, possesses the essentials of an inexhaustible supply of limestone and clay of admirable quality for the manufacture of first-class Portland cement. It is conveniently situated close to the main line of railway to Peshawar, and a new station has recently been opened by the N.W. Railway, called Wah. Ample sidings have been provided to serve the company's works and the quarries of the Wah Stone Quarry and Lime Co., Ltd., which adjoin the cement company's site. An abundant supply of clear cold water is available from the Chablat river which is fed by innumerable and copious springs, whose source is the snowy ranges of the Himalayas.

THE MACHINERY AT WORK.

On this site have sprung up in the last 12 months a number of buildings wherein machines will be installed and the various processes will be performed.

Taken in order, there will be first the Raw Mill, a 50ft. high building of brick, where blocks of limestone from the hill are to be broken by giant jawcrushers, situated below ground level, into pieces the size of a man's hand and less. By means of 50ft. elevators these will be fed together with clay pumped from the Clay Wash Mill, into the komignors and tubemills, revolving drums, in which the mixture is to be ground by means of hardened steel balls and flint pebbles, to a pasty slurry of the consistency of pea-soup. Passing from these mills, the "soup" will be "agitated" in circular vats 66ft. in circumference by means of compressed

air and stirring arms to churn the liquid to an "intimate" mixture of the particles of lime and clay. On the correctness of the proportions of these ingredients depends in a large measure the quality of the cement produced, and here any want of knowledge or carelessness on the part of the chemists, who are continually testing and adjusting the mixture day and night, would have disastrous effects.

The next building is the Kiln House, some 200 feet in length and 50 in height. Here the slurry from the correction vats will be raised by pumps to the Kiln feed to disappear into the revolving steel cylinder, 170ft. long and 7ft. to 8ft. in diameter, known as the rotary kiln. This is in appearance a giant telescope on massive concrete foundations sloping gently from the "eyepiece" or "feed" end to the "objective" or "firing" end. Down this cylinder, as it revolves, first flows the slurry which, as the moisture is driven off on meeting the heat of the 15ft. flame of coal dust and air which is blown through the kiln from the firing platform, gradually becomes "clinker."

From the kiln the burnt clinker will drop to the "clinker cooler"—another rotating cylinder where it will meet a refreshing blast of cool air from a fan, and thence to a shaking conveyor which jerks the now cooled clinker to a hopper, whence it will be elevated to the cement mills. Here it is finally pulverised to the fineness required for "Portland Cement," as known to the general public.

It now remains for it to be stored in silos and thence automatically weighed into those familiar bags in which it reaches the consumer.

The whole of the plant will be driven electrically by a steam-driven turbo-generator of 1,500 K.W.—probably the most modern unit of its type in the Punjab.

The staff employed has had a wide experience, not only of cement manufacture, but of its manufacture under Indian conditions at the Bundi Portland Cement Co.'s works in Rajputana, which are under the control of the same agents and where the best cement so far made in India is produced.

STAMPING PRACTICE IN BRITAIN AND AMERICA.

In instituting a comparison between the stamps and stamping processes current in the United States and those of this country, several interesting features claim attention.

In this country, the gravity drop type is the only kind of stamp. The mechanisms for lifting the tup fall into three categories: (a) the kick stamp with a simple belt taken over a friction pulley; (b) the steam lifter with rotary piston; and (c) the friction lift with power clutch. It should be noted, however, that types (b) and (c) are rapidly superseding type (a) in all but the smallest sizes.

There are but two types of stamp in general use in the United States—the friction stamp known as the board drop, and a specially designed steam hammer. Both of these are arranged to be worked by the stamper himself, and even where assistants are necessary to handle the job, the control, generally by foot lever, is under the stamper.

In the board drop and other gravity stamps the velocity of striking depends solely on the height of the drop; but in the steam stamp the steam is used to raise the tup and also to force it down. Hence for a given striking velocity a shorter stroke can be used, and the time taken by both up and down strokes proportionately reduced. Blows can therefore be obtained more rapidly from the steam stamp, which is a definite advantage as regards output. The American board drop is usually 5 to 6 ft., as compared with the drop of 7 ft. which is the rule with gravity stamps in this country.

American stamps differ in construction very considerably from common British practice. In America the stamps are built entirely on their anvil blocks, while British drop stamps follow steam-hammer practice. Foundation elasticity is obtained in the United States by the expensive expedient of bedding on timber to a depth of several feet; but their method of fitting the tup guides to substantial headgear-carrying supports has many points of advantage.

Turning to the actual stamping processes, an outstanding feature of American practice is the preliminary forming, as well as the stamping of the article, as far as possible under the same stamp. A variant on the older method of using a dummying stamp alongside the main stamp is to use a fast-running steam-hammer for preparing a method by which a much bigger output per stamp is often obtained.

Summing up, the chief advantages of American processes would appear to be (a) rapidity of stroke due to reduction of drop; (b) rigid holding of the bottom die and correct guiding; (c) reduction of interruptions due to more effective preparation

International Theatre.' (Chairman: Sir Cecil Smith. Tuesday, June 13th—Mr. H. Granville-Barker. 'Co-operation in the Theatre.' (Chairman: Lord Crawford. GENERAL NOTES.

VICTORIA AND ALBERT MUSEUM: INTERNATIONAL THEATRE EXHIBITION.—The International Theatre Exhibition at the Victoria and Albert Museum, will be open free daily to the public from June 3rd to July 16th. The large expenses of the Exhibition are being met entirely by private subscription, and subscribers of £1 and upwards will receive two tickets covering admission to a course of six lectures which will be given in the six weeks during which the Exhibition is open. Subscriptions should be sent to Lord Howard de Walden, The British Drama League, 10, King Street, W.C. 2. The Lectures will be at 5 p.m., as follows:—Tuesday, June 6th—Mr. Gordon Craig, 'The

In forwarding the foregoing figures, the United States Consul at Pernambuco remarks that, with the exception of the figures for Bahia, all the quantities given are of babassu nuts.

PROPOSED RAILWAY TO MECCA.—A group of wealthy Arab residents of Mecca is reported to have been organised recently in order to undertake an extension of the railway from Medina to Mecca—a distance of about 375 miles. This extension, writes the United States Consul at Aden, would give Mecca rail connection with Damascus and Aleppo, and thence with Scutari on the Bosphorus, opposite Constantinople.

EXPERIMENTAL COTTAGES.—In 1918 the Department of Scientific and Industrial Research was approached by the Ministry of Agriculture and Fisheries with a view to co-operation in erecting a few experimental cottages to test various methods of building with local materials, and such new construction of floors, roofing, etc., as might be thought promising. Of the 33 cottages erected by the Ministry by direct labour, and forming the Farm Colony at Amesbury, 5 were constructed to the designs of the Department of Scientific and Industrial Research. Without expressing any opinion on the success or failure of the experimental features the Department considers that a description of the work may be of general interest, and the report prepared by Mr. W. R. Jaggard, who was Architectural Consultant, is now published. The external walls of the several cottages were of brick, concrete, chalk and cement, rammed chalk and straw, and chalk pisé, respectively. Various experimental designs of floors, roofs, stairs, fittings and heating appliances have been used. The report gives descriptions of all the cottages and of the experimental features embodied, and where possible, relative costs of the different methods employed. It is illustrated by 93 photographs and drawings, and may be obtained from H M Stationery Office.

PLATINUM IN BRAZIL.—It was recently reported that platinum has been discovered in the State of Parahyba do Norte, Brazil. According to the United States Consul at Pernambuco, the deposit is on a mountain ridge three miles from the main motor road leading from Campina Grande to Patos. Regular transport services now operate over this road, and it is understood that a branch from the main road to the deposit could be easily constructed. For the present the owner proposes to establish an extracting plant at the deposit and bring the ore out by truck.

FIBROFERRITE.—A newly discovered metalliferous substance possessing unusually strong solvent properties is being prepared for commercial use at Central Greta, New South Wales (about 125 miles from Sydney), writes the United States Consul at Sydney, and gives promise of the development of extensive new industries. This mineral, known as fibro-ferrite, is composed so it is stated, of ferrous sulphate, 50 per cent.; oil of vitriol, 15 per cent.; ferric sulphate, 10 per cent.; and several alums and sulphur compounds. It is a very potent combination when used as a solvent for various organic substances, and the constituents of the mineral are already being employed in the manufacture of red oxide of iron, disinfectants, dyestuffs, and copperas. Four patents have been obtained for the use of the mineral, great quantities of which are deposited in the Greta district.

MEETINGS OF OTHER SOCIETIES FOR THE ENSUING WEEK.

- TUESDAY, JUNE 6.** Royal Institution, Albemarle Street, W., 3 p.m. Sir Percy Sykes, "The Foundation of the Persian Empire."
Alpine Club, 23, Savile Row, W., 8.30 p.m. Rev. Canon G. M. Bell, "An Adventure in the Dent Blanche."
Anglo-French Society, Scala House, Tottenham Street, W., 6.15 p.m. M. Maurice Thiéry, "Le Théâtre de Maurice Donnay."
- WEDNESDAY, JUNE 7.** University of London, at the Imperial College of Science and Technology, South Kensington, S.W., 5.15 p.m. Dr. A. F. Holleman, "Recent Investigations on the Substitution in the Benzene Nucleus." At University College, Gower Street, W.C., 5.30 p.m. Prof. T. Borenius, "Past History of Art Teaching." (Lecture III.)
Archaeological Institute, at the Society of Antiquaries, Burlington House, Piccadilly, W., 4.30 p.m. Mr. E. W. Lovegrove, "Eleventh Century Work at Chester Cathedral."
Public Analysts, Society of, at the Chemical Society, Burlington House, Piccadilly, W., 8 p.m.
Electrical Engineers, Institution of, Savoy Place, Victoria Embankment, W.C. (Wireless Section), 6 p.m. 1. Mr. N. Lea, "The Performance of a Radio-Telegraphic Transmitter, with special reference to the New Installation at North Foreland." 2. Prof. C. F. Jenkin, "A Dynamic Model of Tuned Electrical Circuits."
Public Analysts, Society of, at the Chemical Society, Burlington House, Piccadilly, W., 8 p.m. 1. Dr. J. C. Thresh, "The Action of Natural Waters on Lead." 2. Dr. H. E. Annett and Mr. M. N. Bose, "The Estimation of Meconic Acid in Opium." 3. Dr. A. F. Joseph and Mr. F. J. Martin, "The Composition of Cows' Milk in the Sudan." 4. Mr. W. Singleton, "The Use of the Daylight Lamp in Volumetric and Colorimetric Analysis." Literature, Royal Society of, 2, Bloomsbury Square, W.C. 1., 5 p.m. Mr. H. Granville-Barker, "Some Tasks for Dramatic Scholarship."
- THURSDAY, JUNE 8.** University of London, at King's College for Women, Campden Hill Road, W., 4.30 p.m. Prof. V. H. Mottram, "Metabolism of Fat and Allied Substances." (Lecture VII.)
British Architects, Royal Institute of, 9, Conduit Street, W., 5 p.m. Mr. D. S. Maccoll, "What is Architectural Design?"
Historical Society, 22, Russell Square, W.C., 5 p.m. The Alexander Prize Essay.
Optical Society, at the Imperial College of Science and Technology, South Kensington, S.W., 7.30 p.m. Joint Conference between Ophthalmologists and Opticians on Spectacle Construction.
Royal Institution, Albemarle Street, W., 3 p.m. Rev. Dean Inge, "Theocracy." (Lecture III.)
Chemical Society, at the Institution of Mechanical Engineers, Storey's Gate, S.W., 8 p.m. Dr. H. H. Dale, "Chemical and Physiological Properties."
- FRIDAY, JUNE 9.** Royal Institution, Albemarle Street, W., 9 p.m. Prof. J. Barcroft, "Physiological Effects at High Altitudes in Peru."
Astronomical Society, Burlington House, Piccadilly, W., 5 p.m.
Malacological Society, at the Linnean Society, Burlington House, Piccadilly, W., 8 p.m.
Geologists Association, University College, Gower Street, W.C., 7.30 p.m. 1. Dr. A. E. Trueman, "The Llanes Rocks of Glamorgan." 2. Mr. C. C. Fagg, "The Ecession of the Chalk Escarpment and the Development of Valleys in the Chalk between the Moie and the Darent." 3. Mr. C. C. Fagg, "The Ecession of the Chalk Escarpment and the Development of Valleys in the Chalk between the Moie and the Darent."
Physical Society, Imperial College of Science and Technology, South Kensington, S.W., 5 p.m.
- SATURDAY, JUNE 10.** Royal Institution, Albemarle Street, W., 3 p.m. Sir Hugh Allen, "Early Keyboard Music." (Lecture III.)
Municipal and County Engineers, Eastern District Meeting, at Harwich.

FRIDAY, JUNE 9, 1922.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C. (2)

NOTICE.

TWENTY-FOURTH ORDINARY MEETING.

WEDNESDAY, MAY 31st, 1922; SIR CHARLES J. HOLMES, D.Litt., F.S.A., Director of the National Gallery, in the chair.

The following candidates were proposed for election as Fellows of the Society:—
Chaudhuri, S.N., M.A., Calcutta, India.
Stannard, H. Sylvester, Bedford.

The following candidates were balloted for and duly elected Fellows of the Society:—
Hansard, John Henry, Bookham, Surrey.
Munshi, Trambakrai M., London.
Ryland, John William, J.P., F.S.A., Rowington, Warwick.

A paper on "The Problem of Provincial Galleries and Art Museums, with special reference to Manchester" was read by MR. LAWRENCE HAWARD, M.A., Curator of the City Art Gallery, Manchester.

The paper and discussion will be published in a subsequent number of the *Journal*.

PROCEEDINGS OF THE SOCIETY.

DOMINIONS AND COLONIES AND INDIAN SECTIONS.

(Joint Meeting).

FRIDAY, MAY 5TH, 1922.

THE RT. HON. VISCOUNT BURNHAM, C.H., President of the Empire Press Union, in the chair.

THE CHAIRMAN said that as President of the Empire Press Union it was a peculiar pleasure to him to preside on the present occasion, because the newspaper press of the entire world took the greatest interest in the developments of wireless telegraphy and were all well aware of the immense services that had been rendered by Dr. Eccles to make it serviceable, not only for their purposes, but for mankind in general.

The paper read was:—

IMPERIAL WIRELESS COMMUNICATION.

By PROFESSOR W. H. ECCLES, D.Sc., F.R.S.,

Vice-Chairman of the Wireless Telegraphy Commission.

In addressing the Dominions and Colonies and Indian Sections of the Royal Society of Arts on the subject of Imperial Wireless Communication, I know that I am speaking to those who have more to do with policy than I have, and I shall, therefore, limit myself to a plain statement of the facts which ought to be in the possession of those who wish to form their own opinion upon the proposal to erect an Imperial Chain of Wireless Stations. These facts are mostly historical, scientific and technical, but some of them have legal and economic bearings.

The science of wireless telegraphy began its experimental career when Hertz showed, in 1888, that electric waves can be made at one place and perceived at another. It is almost as easy as dropping a pebble into a quiet pond and watching the water waves arrive at the other side of the pond. Branly and Oliver Lodge, about 1890, invented a sensitive means of detecting the waves (called the "coherer"), and Lodge, in 1894, transmitted signals and recorded them across a distance of 60 yards. Far-seeing thinkers like Crookes then immediately foreshadowed world-wide wireless telegraphy conducted by aid of tuned apparatus, but offered no practical suggestions. For all we knew, centuries might have passed before wireless telegraphy could be developed to span a hundred miles, although investigations were then in progress in many laboratories.

But among those investigators there was one pre-eminently gifted with faith and insight and inventiveness whose work soon became world famous. Senator Marconi, as we know him now, about 1896, discovered the principle of the earthed aerial.

or antenna, raised Hertz's laboratory work to an engineering scale, and improved the coherer greatly. He thought of and tested innumerable things, selected with uncanny foresight those that were going to be practical, and, in fact, found what still appear to be the only possible paths through the jungle which Nature presents to every investigator and inventor in a really new branch of endeavour. I recall with personal gratification, that after a considerable training in Hertzian waves I joined Marconi's staff about the time he was developing tuning, and was amazed at the way in which high frequency currents were being handled; and although I was with him less than a year I learned sufficient to revolutionise my point of view. During the years between 1896 and 1910, Marconi, aided by Lodge's invention of the tuning coil, carried wireless telegraphy substantially to its present form:—(1) a means of generating electrical oscillations; (2) an elevated conductor (called the antenna) for making electric waves that will spread in all directions; (3) means for collecting the waves at the receiving station—usually an elevated conductor—and (4) means for detecting and making evident the arrival of waves. Meanwhile, other inventors had been at work in nearly every country and had made valuable contributions, but they scarcely deflected the progress of their leader. Poulsen's arc transmitter is the chief of the other contributions. By 1909 the Atlantic had been spanned satisfactorily, and other oceans attempted; in short, wireless telegraphy had grown up in about the same interval of time as was taken by the Watt steam engine.

Indeed, before the end of 1909 the prospect of a fight between the cable and wireless was debated everywhere and the experience accumulated by various governments and companies was such that the feasibility of establishing wireless communication between the parts of our scattered Empire became apparent. In March, 1910, the Marconi Company applied to the Colonial Office for permission to erect a number of large wireless stations for providing communication between the most important parts of the Empire. The matter was passed to the Cable Landing Rights Committee and was also discussed by the Committee of Imperial Defence during 1910 and 1911. In June, 1911, the Imperial Conference

passed a resolution that a State-owned wireless chain should be established, and a joint committee was then appointed representing Government Departments, Australia, New Zealand, South Africa and India. This committee, which was called the Imperial Wireless Committee, requested the Post Office to prepare terms upon which negotiations might be opened with the Marconi Company. The terms so prepared were considered by the Cable Landing Rights Committee, who asked the Postmaster General to enter upon the negotiations with the Company.

In July, 1912, an agreement between the Postmaster General and the Company was signed under which the Company was to erect forthwith stations in England, Egypt or Cyprus, Aden, Bangalore, South Africa and Singapore; and others were to follow. The stations were to be capable of maintaining uninterrupted intercommunication throughout the 24 hours and were to work duplex and high speed during a portion of each day. This contract was not ratified by Parliament; a Select Committee of the House of Commons discussed it throughout the winter of 1912-13, and an Advisory Committee presided over by Lord Parker and including several experienced engineers and scientists discussed the technical and the patent aspects of the contract. In consequence a second contract was agreed upon between the Postmaster General and the Company and this was ratified by the House of Commons on the 8th August, 1913. Work began at Leafeld in March, 1914, a station in Egypt was commenced a little later, and sites were provisionally selected in East Africa, South Africa and the Straits. But at the end of 1914 and in January, 1915, the Post Office informed the Company that the Government had decided not to go on with the work, and the Company thereupon intimated that they would claim compensation for breach of the contract.

The war was now compelling attention to wireless telegraphy in every aspect. The Admiralty set up a dozen medium power stations at well distributed points of the Empire, the Marconi Company being the contractors. There were many new inventions and many novel applications, nearly all of them improvements of apparatus and methods existing before the war. The chief improvements were in the detail design of the audion and its associated

circuits and these improvements greatly enhanced the practicability of wireless. The audion was introduced in 1907 by the American inventor de Forest as an improvement of the Fleming valve, that is as a rectifier, but became finally a fundamentally different apparatus utilising phenomena that make it a useful magnifier of electric currents. Different makers name it a "pliotron," a "three electrode vacuum tube," a "three electrode lamp," or a "three electrode valve." The official international name is "triode" or "triode valve," but in English wireless slang it is frequently called a "valve." Its essential valuable characteristic is that it amplifies currents. In small sizes it is used for reception and enables very feeble signals to be made audible. In large sizes it is employed for transmission. This is done by taking a portion of the existing oscillation, feeding it to the input side of the triode valve and adding the magnified result to the original oscillation, all in a continuous manner. The energy is supplied from a direct current battery and the magnifying process goes on until a certain limit is attained determined by the sizes of the battery, the triode valve and other parts of the apparatus. This feed back method of strengthening and sustaining oscillations was invented by Armstrong in America and by Meissner in Germany independently in the spring of 1913 and also by Langmuir in America in October of the same year. It enables the triode valve to be used not only as a rectifier and an amplifier, but also as a converter of direct current into current oscillating at any desired frequency.

The war greatly accelerated the development of these pre-war inventions, and nowhere was progress more rapid than in the Radio-telegraphic laboratory of the French Army. Here, under the guidance of General Ferrié, the valve, or lamp, as the French call it, was pushed to perfection in the construction of amplifiers and other apparatus for the reception of signals. The apparatus in use to-day for these purposes remains much the same as at the date of the Armistice. The basic inventions of Marconi, Lodge and Poulsen, have become more and more valuable in consequence of improvements brought about by the triode valve, and in the sending plant as well as in the receiving apparatus.

Meanwhile, although work on our Imperial Chain has been suspended, America,

France, Germany and Italy found it necessary to press on during the war with their corresponding schemes. As it stands now, the American Navy's strategic and partly commercial Chain comprises six first-class stations and a larger number of second-class stations. The first-class stations link Washington with Central America and California, and through Honolulu and Guam with the Philippines. The terminal station has a 500 kilowatt arc, and is less than 2,000 miles from Peking, Tokio, India and Northern Australia. Most of the steps of the Pacific Chain are of the 2,000 mile order, but there is one big step of 4,600 miles, from Honolulu to Guam.

The French Military Chain is now nearly completed, much of it having been planned since the Armistice. Paris is, or will shortly be, linked by first-class stations with the Soudan, the Congo, Antananarivo, Pondicherry and Cochin China. All these steps are of the 2,000 mile order or less, except that from Antananarivo to Pondicherry, which is 3,100 miles. Besides the Military Chain, France possesses a first-class Naval station at Nantes, and two magnificent stations at Bordeaux and Lyons, controlled by the Department of Posts and Telegraphs.

The Italian State-owned scheme embraces two modern stations in Italy, and two spark ones in North East Africa. The Rome station was built by Mr. Elwell during the war, and the Coltano station is being re-equipped by the Marconi Company. The largest distance between the Italian stations is about 2,500 miles. The German Chain contemplated three stations in Africa, one in the Java Seas and one in Yap. Those which were erected were lost during the war. The distance from the Nauen station to the Kamina station is 3,400 miles, and proved too great for real work. Windhuk is nearly 2,000 miles south of Kamina, and is believed to have exchanged scarcely any signals successfully during its short active life.

At the time these various wireless networks were being laid down or completed by foreign Governments, the British Post Office obtained a grant of £170,000 for equipping with arcs the Leafeld and Cairo stations, abandoned in the first year of the war, and the Marconi Company brought their long-deferred action for damages for breach of contract and went before Mr. Justice A. T. Lawrence with the Petition of Right. The Arbitrator awarded in July, 1919,

the sum of £590,000 to the Company, as his estimate of the present worth of all the royalties which the Company would have received under the contract.

The Government now decided to take up again the problem of the Imperial Chain. They had before them the advice of the Parker Committee of date 1913, and there was the experience of the war and of other countries. The Parker Report stated that the Marconi Company were, in 1913, the only firm doing business in this country able to erect at once stations of the necessary magnitude; but it added some comments which probably influenced later decisions. The Report (paragraph 9) points out that in order to get the best results it would probably be desirable to "combine apparatus, the combination of which is difficult, if not impossible, because of the existence of patent rights." A notorious example of this mode of operation of the patent system is seen in Watt's "sun and planet motion," and there are innumerable others. The Crown, however, cannot be prevented from using any patent. This is an advantage of State ownership arising out of technico-legal considerations, and may perhaps be regarded as worthy to rank with the political and strategical advantages envisaged by the Committee of Imperial Defence.

But in order to obtain up-to-date advice Lord Milner, as Chairman of the Imperial Communications Committee, and with the approval of the Cabinet, appointed in November, 1919, a committee under the chairmanship of Sir Henry Norman to consider afresh the problem of establishing an Imperial Chain of wireless stations. The terms of reference instructed the Committee to consider both strategical and commercial requirements, and to make estimates of costs and of revenue, under any scheme they proposed. Of the strategical requirements, those of the Admiralty were the most stringent, for they desired quick communication with every naval base in the Empire, and with all ships above the class of light cruiser, wherever they may be at sea between latitude 60° N. and latitude 60° S., either direct or through not more than two linking stations. Clearly this last requirement has a bearing on the Admiralty estimates, for if squadrons can be constantly in touch with headquarters, instead of being lost for days or weeks at a time, fewer ships

can do a definite duty. The commercial requirements included the serving of as many communities as possible, the provision of uninterrupted communication at all hours and all seasons, and a large traffic handling capacity. In addition, the scheme should be so economical in capital outlay that it would yield a profit at an early date after interest and amortisation were provided for.

The merely physical problems confronting the Committee may best be described by aid of an analogy. Suppose that a proposal were made to establish telegraphic communication between Hampstead Heath and the Crystal Palace by means of beams of light sent across London. We know that on a dark night with a clear atmosphere, the rays of a single candle would be sufficient to carry signals from either station to the other. But when a thick brown fog hung over the City on a December morning, it would be impossible to pass a signal even by aid of millions of candle power. There are all grades of opacity between these extremes, and, in fact, the candle power found just sufficient for transmission would be different every day. Now, it would be quite true to say of this particular method of signalling between these points, that a telegraphic service was possible with, say, 200 candle power; but everyone knows that at certain seasons there would be good signals only for an hour or two per day, at other seasons for many hours per day, and on rarer occasions a good telegraphic service might be maintained throughout the twenty-four hours. In order to increase the average number of useful daily hours per annum the most natural step would be to set up a relay station—say, on the dome of St. Paul's. The same candle power will pass more messages through the half distance than through the whole distance, and the service would, therefore, be more continuous. The central relay station, would, besides, be able to seize opportunities of any clear intervals that might arise to the north or south of it. The erratic way in which these clear intervals occur in a misty or foggy atmosphere is familiar to every Londoner. It will be admitted that an even better service, reckoned by the average annual hours of effective communication, would be afforded by having more than one intermediate relay station.

All this is but a paraphrase of what occurs on the grand scale in wireless tele-

graphy. Instead of miles we must speak of thousands of miles; instead of patches of fog over parishes we must think in oceans and continents. Instead of the smoky vapours of the Thames we think of electrical fogs extending into the highest atmosphere; fogs that may gather and disperse just as rapidly as the London mists; fogs that have daily and yearly variations as unaccountable as the weather itself.

At this point, the analogy must be dispensed with because there are other electrical difficulties not analogous to the meteorological ones I have just described. For whenever electricity gathers in the atmosphere, electrical discharges from one portion of air to another, or to the earth, are continually taking place, and these generate natural electric waves that course over the earth, agitate the receiving apparatus of wireless stations, and produce noises in the telephone of the operator or marks on the tape of the recorder, which mask or overwhelm the man-made signals. These disturbances, due to natural electric discharges, are spoken of as 'X's' or 'strays' or 'atmospherics.' In these circumstances it is of little use to employ powerful magnifiers of the signals enfeebled by passing through thousands of miles of electrical fog, for the true and the false signals are magnified together. The only hope is to discover and apply methods of discriminating between the true and the false; such methods are being slowly evolved.

As an example of what happens on the large scale, consider the reception in India of signals from England. During December, January and February the conditions in India are very brilliant and every message may be letter perfect at high speed during practically the whole of the twenty-four hours. In March the monsoon approaches and reception becomes gradually worse. During April, May and June the monsoon conditions are establishing themselves and signalling results are very bad indeed, but when fully established, as in July and August, signals are rather better. In September the monsoon begins to withdraw and during this month and October many hours may be lost on many days. November is better but is disturbed by bursts of atmospherics; and now the good time of the year begins again.

The Committee had these considerations before them and studied the views of many

people of experience in these matters. They concluded that if, for example, direct communication were attempted between England and Australia, there could be only a few hours of good service per day on the average and that the owners of the stations would then call for the erection of an intermediate station in India in order to employ their capital to better advantage. A group of five big stations namely, England, Vancouver, Australia, South Africa and India, is an attractive scheme but is open to similar objections—that is to say the annual average of hours of service might be too low to be remunerative, especially if, as must needs be, the stations erected were to be of the largest possible dimensions. The next step is obviously to introduce intermediate relay stations between the big five and to install at all places first-class stations of great but not extreme magnitude. Spent in this way the same money would give, the Committee believed, a more efficient and in the end more speedy service between the principal centres, would bring the communities at the intermediate places into touch with the rest of the Empire, and would more assuredly satisfy the Admiralty's and the other strategic requirements. This distribution of the stations happens to be geographically possible in the case of the British Empire without exceeding 2,800 miles in any step, the average step being about 2,400 miles. This has become known as the 2,000 mile scheme. It happens to coincide with the length of the step aimed at in the American, French and Italian schemes, though some of these were perhaps settled upon later.

But in order to insure uninterrupted service over distances ranging from 2,000 to 2,800 miles at bad times of the day and year the stations would have to be very powerful. After collecting evidence of what was likely to be practicable within a few years they decided to recommend that the plant be designed to deliver 240 kilowatts to a low resistance aerial of great height. If the art had not sufficiently developed by the time erection was in progress, the stations should be built of 120 kilowatts power and be made capable of early enlargement to the full power. Two methods, the Poulsen arc and the triode valve, were especially favoured and considered. They recommended that the triode valve method of generation of oscillations should be employed, if sufficiently developed. If I

may say so this was a very bold move on the part of the Committee for the largest known valve station in existence at that date was probably less than 20 kilowatts in magnitude.

The action of the Committee has doubtless had some influence upon recent developments of big triode valves.

With such stations, the Committee pointed out in their report, each centre would be able to communicate during certain hours of the day with the most distant of its fellow stations; and they expected that by aid of the intermediate stations any two of the centres could get into communication quickly at any time of day or year. On this point, perhaps, the Committee were a little over sanguine—there will be occasional hours, I imagine, when even the more powerful stations will fail to force good signals across 2,800 miles.

The chain of stations as finally recommended by the Committee for immediate erection, consisted of stations in England, Egypt, India, Singapore, Hong Kong, Northern or Western Australia, East Africa and South Africa. The stations in England and in Egypt are to be of the new type and additional to Post Office stations at Leafeld and Cairo. There are thus two branches, an African and an Eastern, meeting in Egypt. The case of Canada was postponed for joint consideration with representatives of the Canadian Government, stations at Montreal and Vancouver being provisionally suggested. In actual operation messages from England to Australia would pass through all the intervening relay stations during the intervals of greatest atmospheric opacity and disturbance, being handled in much the same way as at cable relay stations. During clear intervals one or more of the relay stations would be omitted. Wireless here possesses great advantages over the cable.

The Committee recommended that the Post Office Engineering Department in this country and the corresponding Departments overseas be given responsibility for making contracts with private engineering firms and supervising construction, and further recommended that a small Commission be appointed for planning the stations and advising generally during erection. This, by the way, is in close accord with the principles enunciated by Lord Parker's Committee of 1913 in their valuable Report.

The planning commission was appointed by the Cabinet at the end of 1921, about seven months after the earlier Committee had reported. Lord Milner, in his capacity as Chairman of the Imperial Communications Committee, became Chairman of the Commission. During the past year the Commission have acted, when called upon, as advisers to the Imperial Communications Committee, the Dominions and the Indian Government. Their main work has been of the nature of design and selection of the best apparatus and methods of construction of the Imperial stations within the scope of the preceding Committee's recommendations.

It is with warm appreciation of Lord Milner's trust in the Commission that I recall his instructions that we should choose the most suitable apparatus and methods without constraint and with scrupulous impartiality. The Commission's Report, which was completed in December last, was drafted on the understanding that the work would be carried out by private firms rather than in Government workshops. The outline specifications in the Report leave a wide latitude for firms to submit ideas and processes of their own for the approval of the Commission.

The chief anxiety of the Commission during the past year has been to determine whether or not the equipping and running of triode valve stations of 120 and 240 kilowatts is a practical proposition from every point of view. They have been almost satisfied by witnessing the independent development work of the Signal School and of the Marconi Company. There was sufficient doubt left as regards annual running costs to lead the Commission to recommend that arc stations be temporarily installed in the Nairobi, Singapore and Hong Kong stations, to be converted later to valve stations when these had been proved out in less remote places.

The Commission have had to survey broadly the capability of the industry to meet promptly the probable demands during construction and afterwards. Triode valves in glass can be supplied in ample quantity by the Marconi Osram Valve Company; valves in silica and also in glass can be supplied similarly by the Mullard Radio Valve Company. As regards tall masts, the Elwell firm have erected some of the tallest in America and Europe. As to general wireless plant the Marconi

Company have obtained modern experience of large station work at Carnarvon and Coltano; the Elwell group have been responsible for the construction and installation of vital parts of the big stations at Paris, Lyons, Nantes, Rome, Leafeld and Cairo, as well as several in America. Altogether there is a great body of experience in private firms available for contributing to the construction of the chain stations.

Over and above this the scientific staff of various Departments of the Government have gained much experience during the war and since. The Admiralty Signal School, Portsmouth, is, I believe, well ahead of any firm in the applications of the large silica triode valve. The transmitter erected at the Horsea Experimental Station at the request of the Commission is able to deliver about 100 kilowatts to an antenna and is probably the largest in the world. The Army, at the Signal Experimental Establishment, have developed a type of high speed receiving apparatus of unsurpassed efficacy. The Post Office, in their Research Laboratory, have devised and developed receiving apparatus which has won the admiration of all who have worked with it in this country, in Egypt, India and East Africa. All these improvements, are, I understand, protected by patents of which the Crown has free user.

No discussion of the Imperial Chain would be complete without a reference to the patent situation. I have already indicated that many of the fundamental things of wireless telegraphy are now free for all to use. The elevated conductor, the tuning coil, the arc converter, various detectors, the two electrode valve for rectifying, the triode valve for magnifying, and others, are as free as the steam engine and are relatively as useful. For example, the great new transmitting station near Bordeaux, owned by the French Government, and perhaps the greatest in the world, is, so far as I am aware, quite free from patents. All the transmitting stations of the American chain appear to be similarly free. On the other hand, some, but not all, of the Imperial Chain transmitting stations will employ the Meissner feed-back invention described earlier in this paper, but I am instructed that the rights of this have been acquired by the Marconi Company and that user of it has been paid for by the Crown in the £590,000 awarded to the Company by Mr. Justice Lawrence. I do

not know that any other patent of significance will be employed by the transmitting stations. As regards the receiving stations of the Chain the Meissner patent is again employed (but has been paid for) and the heterodyne patents belonging to the Metropolitan Vickers Company may possibly be held to be concerned. There are two early patents of German origin which may possibly be employed in the Chain stations, one for amplifying oscillations before transmission and another for amplifying the feeble oscillations dealt with in reception, but neither of these is given much weight by the experts in these matters. No other patents of the last class and of outstanding or fundamental importance appear to be employed.

The study of the patent situation leads to a mention of that other kind of monopoly brought about by business and financial combination. Wireless telegraphy lends itself to this type of monopoly very easily, chiefly because there is only a limited number of wave bands available for distribution to powerful stations and there is no room for late applicants. But it appears to me that the way of minimising this danger has been indicated by America and France. These and other nations have established first their State-owned chains, and after thus ensuring the national security and other national interests, have proceeded to give facilities to commercial firms wishing to undertake telegraphic business. The competition in efficiency of two independent schemes, one national and the other private, cannot but be beneficial to both and to the public interest.

I think that the facts I have now laid before you explain why a long succession of Committees and Conferences, including the Imperial Conferences of 1911 and 1921, have all decided that the Imperial Chain should be State-owned. The chief reasons are strategical, political and technical. The strategical point of view needs no emphasis; the political advantage of State-ownership is that only in this way can Empire telegrams be ensured such a measure of priority or preference as will stimulate inter-Imperial trade and foster feelings of kinship. As regards the technical advantages, in the first place the Crown alone can, without fear of injunction, select and combine the best apparatus of rival systems; and in the second place, only the Crown can call upon and unite

the stored knowledge and experience of all the Companies and all the Government Departments in every Dominion. Moreover, only the Crown can do level justice to all the competing private interests.

I must not close without referring to that marvellous feature possessed exclusively by wireless and known as "broadcasting." A wireless station shouts to all the world and wireless is therefore going to share with the Press the moulding of public opinion. When an Imperial news service has been organised, every newspaper office in every Colony will pick up its news by aid of inexpensive receiving apparatus. I venture to suggest to our Chairman, who is President of the Empire Press Union, that the Union have here great scope for constructive organising work. I suggest also, that they could make a good case for the transmission of general press messages at a very low charge per word during those parts of the day unsuitable for the perfect accuracy demanded by coded and high speed private and official messages. But not only that; broadcasted news is intercepted with avidity by the vernacular press in many countries, as Lord Northcliffe has pointed out, and thus by means of the Imperial stations, British national advertisement and other propaganda will take their place in influencing foreign opinion and the flow of trade.

But what will, I think, appeal strongly to the Dominions and Colonies and Indian Sections of this Society, is the fact that anyone who wishes will be able to pick up the news for himself if there is no local newspaper to do it for him. And thus the ranches of Canada, the homesteads throughout Australasia, the settlers scattered from Rhodesia to the Cape and the lonely Englishman in remote provinces of the Indian Empire, will be able to receive the news from London as quickly as can many an English village.

DISCUSSION.

THE CHAIRMAN (Viscount Burnham) said that, as Mr. Balfour used to say, he was a child in those high matters, but he was a child of Fleet Street, and that made him deeply concerned in all Dr. Eccles had told them. He did not know that he was much alarmed by the menace with which the paper terminated. He did not think the broadcasting of news would be much of a danger to the Press as an alternative method of public information. He thought the broadcasting of news would only be effective

as handled by the Press, and he hoped and believed they would be equal to the emergency. He still regarded wireless as the greatest wonder of the world. Wireless telegraphy had developed with wonderful rapidity, but not quite as fast as was anticipated by Senator Marconi when he addressed the Imperial Press Conference in 1899, and he (Viscount Burnham) was in the chair then, and told them he would be able to give them a regular and reliable service of news by the autumn. Senator Marconi was only a little previous. Accustomed as they had been of late years to the marvellous advances of applied science, it seemed almost incredible that Marconi's first patent was only taken out in 1896. It was only in that year that Sir William Preece invited Signor Marconi to send messages across the Bristol Channel. Two years subsequently installations were set up between the South Foreland and the East Goodwin light-vessel and the South Foreland and Wimereux in France. The system was largely used during the naval manœuvres of 1899 and definitely adopted by the Admiralty in 1900. It was employed during the Boer War. In 1901 it was already at work on 37 ships of the British Navy; it was part of the regular service of the Governments of Germany and France, and in June of that year the first Atlantic liner belonging to Great Britain sailing between Liverpool and New York was equipped with it. It had already been installed on the Norddeutscher Lloyd mail steamer, Kaiser Wilhelm der Grosse, and even the Germans were making use of it commercially to and from ships at sea, and the Belgians with their Princess Clementine found it practicable to communicate to Dover Harbour from La Panne—70 kilometres away; and on more than one occasion, although the S.O.S. signal had not then been thought of, the lives of shipwrecked mariners were saved by wireless messages summoning assistance to their relief. The Prince of Wales was not the first member of his family to be made acquainted with the wonders of wireless, because when the present King and Queen went to Australia, as the Duke and Duchess of Cornwall and York, the Marconi system was used during the voyage. When their son, the Prince of Wales, went to the Antipodes in the Renown, there were many times points on the journey which could only be reached by wireless. It might not be out of place to recall the early efforts of the *Daily Telegraph* to make practical use of the new telegraphy in the interests of meteorology. Scientific experts had placed it on record that the time had arrived for trying the efficiency of wireless telegraphy in providing advanced news of the weather in the Atlantic, and pleaded that there should be no unnecessary delay in organising the practical experiment. The report of the Committee appointed by the then Prime Minister was published in June, 1904. The Editor put himself into communication with the

Marconi Company and the great shipping lines, and on August 6th of that year the *Daily Telegraph* printed the first wireless telegram from the Atlantic, sent by the Allan Liner 'Tunisian'. The first message was actually received on August 4th from latitude 56 degrees N. and longitude 20 degrees W., and was timed noon: a later Marconigram came to hand at midnight and on Sunday at noon a third message from latitude 56 degrees N., longitude 9 degrees W., was received. These messages were despatched at a distance of about 70 miles from the mainland. They were received at Malin and thence transmitted by ordinary postal telegraph lines. The limit of distance was regulated by the transmitting power on board the steamer, but there was no such restriction of power transmission on land and the messages despatched were received on board ship at a distance of 2,250 miles. History had recorded the first attempt to span the Atlantic. It was on Wednesday, December 11th, 1901, that the pre-arranged signal—the letter S in the Morse code—was repeatedly received across the wide expanse of ocean lying between Poldhu and Newfoundland. A kite was used as the aerial. All these early experiments had to do with the sea and not with land. The most confident anticipations were formed of the future use of wireless to and from ships, and these had been more than fulfilled. Every night from both sides of the Atlantic news was flashed to be reproduced in the newspapers published on the great liners or in the news bulletins in the smaller steamships: and he might tell them that there was acute competition going on now among the newspapers as to who should supply the wireless that was being used on board the different liners of ships, because, obviously, it had a great publicity value—he might say quite frankly—for advertising purposes. The broadcasting of news had become a big business since the Great War, when wireless was of immense service in propaganda. It was still employed for similar purposes, not merely by Governments, but by great trading corporations. Everybody knew that that tendency with the tremendous emulation in advertising values was bound to increase rapidly. Looking back at their own experiments it was interesting to note that every day the Air Ministry compiled its meteorological forecast from wireless reports. There was another Press aspect. They often in the days gone by had read their paper in the morning, especially in the winter time, and had to do without the cabled news from some important foreign parts. Well now, of course, wireless competed with the cable, and sometimes one wins and sometimes the other. Repeatedly when land wires, feeding the cables were down during wind storms, the wireless, subject to no such disability, came to the assistance of the newspapers. It was rarely that one had to print nowadays "No news was received last night from Paris, because of the interruptions.

to the 'Special Wire.' They all knew that wireless had troubles of its own, but the competition between the cable and wireless gave them of the Press much greater regularity and certainty in the reception of their special news than they ever had before. Every day brought them fresh developments. They knew now that they could have wireless telephones in their homes. Already, as the members of the many distinct wireless societies would tell them, members who had reinstalled their wireless sets might enjoy concerts by wireless for about a quarter of an hour once a week. The time was limited by regulations, which, he took it, were going to be revised. Even then, of course, they would have nothing like the facilities, the embarrassing facilities, which they heard were enjoyed in the United States. They might suffer from what Bismarck called the "spirit of the green table," because regulations often stood in the way of progress. In America government counted for much less and there was no Government control, and there wireless telephony was becoming, it was said, a form of furore. The other day he read of how the police were making use of wireless to draw a girdle around the earth. In Paris they did so with a motor-conveyed transmitter in conjunction with an aeroplane: it was high time they did so, for not a few fugitives from justice had fled from this country by air express and had been followed by wireless. Soon, too, he supposed, every policeman would be a walking "wireless set," in direct touch with all the world. The newspapers of yesterday and today were remarkably full of news of wireless developments. There was, of course, the speech of the Postmaster-General in the House of Commons, and although the proposed installation of broadcasting stations was not yet defined, it might include the dissemination of all classes of news. Secondly, there was the promise of secrecy to be obtained by short wave lengths, as explained in a remarkable paper by Mr. Franklin. Thirdly, they were reminded of the frequency, or rather the frequent possibilities, of saving life at sea by summoning doctors to vessels for urgent operations; in the last few weeks there had been a good deal of discussion on this subject; and, lastly, there had been, what he had mentioned, the immediate introduction of wireless into the home for the purposes of family entertainment. They who had been on the prairie could imagine what a tremendous relief that would be to the monotony of life which the settlers in the scattered and far distant parts of the Empire suffered from now. Re-visiting Canada after 25 years he saw what a difference had been made in the life of the prairie farm by the telephone and the motor car. When in addition to that the amenities of wireless were provided, there would not be the same craving perhaps for the movies and the street lamps which prevented so many good Englishmen

making the great adventure with their wives and families on the trackless wastes which awaited cultivation and development all over the English world. He was sure he expressed what they all felt in their hearts when he said that there could be no more important subject for their discussion and none destined more to change the conditions of human life and profoundly to modify the progress of their civilisation. They were unusually fortunate in the number of men of great knowledge who were there that day, and he was certain that the man they would like to hear first and most was the man to whom they owed so much of the developments that they had been talking about—Senator Marconi.

SENATOR G. MARCONI, G.C.V.O., thanked Viscount Burnham very sincerely for the kind things he had said about the speaker's long connection with wireless telegraphy, and also for the very interesting résumé his lordship had given of the developments of wireless telegraphy during the last twenty or twenty-five years. If progress sometimes had not been quite as rapid as he would have desired, perhaps Lord Burnham would agree that that had not always been the fault of the inventor: other influences had sometimes kept it back. He had always found Lord Burnham most sympathetic, most enterprising, and most ready to test anything that was useful, and to publish and give credit for any good result obtained. In that respect he had been a real friend to the progress of the new art of communication. With reference to the paper, he desired to express his thanks to the author for the kind words he had used regarding his (Senator Marconi's) work in radiotelegraphy. He was glad that a man of such scientific attainments had remained faithful to the fascinating subject of wireless. He could not help, however, disagreeing with the author's views with regard to the limitation of the range of wireless stations, because, in his opinion, there was no range on earth that could not be covered satisfactorily if stations employing adequate power and equipped with suitable apparatus were constructed. As the author had recalled the fact that he (Senator Marconi) had had the privilege of having him as his assistant for a short period many years ago, Dr. Eccles would perhaps agree that reliable communication could at present be achieved over distances which would have seemed to him, as to almost anyone else at that time, very doubtful, if not impossible. The increase in the ranges at which signals could be occasionally received was not so great, since the early days of wireless, as the increase in the ranges at which reliable communication could now be carried on throughout the year. But even now new methods were being developed which, for in-

stance, might cause an entire departure from the current practice in radiotelegraphy, and those methods might differ as much from the methods now in use as the latter did from the arrangements in current use twenty years ago. The author, in explaining the variability in the range of wireless telegraphy, had made an analogy which he did not consider quite fair, namely, the analogy of the transmission of light in a place like London or any other place during clear weather and in foggy weather. A strong light might be seen on a clear day for twenty miles or so, but on the advent of a thick fog that distance might be cut down to one hundredth part, or even less, of twenty miles. But that extent of reduction never occurred in his experience in wireless telegraphy, and if it were the case, at least one hundred intermediate stations would be required between this country and Australia. He did not desire the author to be misunderstood when he stated that the electrical difficulties were much greater than the meteorological ones to which he had just referred. He believed there was no case in which the range of a big station was brought down to one-hundredth or one-thousandth of its working range. It was those facts that made him consider that perhaps the author was more pessimistic than he ought to be when speaking of the possible reliable range of long-distance radiotelegraphic stations. In conclusion, he desired to say that he had listened with the greatest interest to the description given of the schemes for bettering and facilitating communication between different parts of the British Empire and different parts of the world.

MR. ALAN A. CAMPBELL SWINTON, F.R.S. (Chairman of the Council), congratulated the Society on the very interesting paper that had been read, and on the fact of so many eminent and distinguished gentlemen being present to listen to it, a result largely due to the persistence of the Secretary of the Sections, Mr. Digby. The author had referred to the earlier experimental work carried out by Hertz in 1888, but it was not well known that in 1879 Professor David Hughes also made certain very interesting experiments on the subject of wireless telegraphy. He did not publish the results of those experiments, and priority could not, therefore, be claimed for them. Nevertheless, it was an interesting fact that quite recently a number of his notebooks had come into the possession of the British Museum, which he (Mr. Campbell Swinton) was requested to investigate with the object of seeing whether they were of sufficient value for the British Museum to include in its collection. On examination, he found a complete account made by Hughes at the time of all the experiments he had carried out and of the various people he asked to see them. They completely verified the fact that while Hughes thought the result he obtained was due to conduction

through the air, and had no idea that electrical waves entered into the matter at all, Hughes did manage to transmit signals from his house through space over three or four hundred yards; in fact, he carried out practically the same sort of experiment that Lodge made a great many years later. The notebooks showed that Hughes had made a certain amount of apparatus, and he (Mr. Campbell Swinton) having been informed that the notebooks had been rescued from an incredible mass of useless lumber, made enquiries and discovered a room full of Hughes's effects. On looking through them the actual apparatus with which Hughes made his experiments were found, and he was happy to state that the trustees of Mrs. Hughes, to whom the instruments belonged, had presented them to the Science Museum.

MR. GODFREY ISAACS said he was sure the author would forgive him if, in dealing with a subject of such importance, he did not indulge in idle compliments, but said what he thought about the paper which had been read. In order to get a true understanding of the paper, one had to survey for a moment the whole position in respect of the Imperial chain of stations, as recommended by the Commission. As they knew, Canada abstained, at least for the present; Australia, India and South Africa had all condemned the Committee's recommendations and had resolved upon direct communication. Australia had already joined with private enterprise and entered into an agreement for the provision and working of stations for direct service. In those circumstances one could conceive that it had been thought desirable to put up some defence to the Committee's recommendations which India and the Dominions declined to adopt. The author, therefore, had read a paper with the object of making a plain statement of facts which ought to be in possession of those who wished to form their own opinion. In order that everybody might be in a position to form his own opinion, it was essential that the facts he had before him should be accurate. Personally he was afraid that the information with which the author had been furnished had led him into errors which might also be misleading to those who heard or read the paper. One would be led to suppose that America and France commenced by erecting wireless stations for commercial services which would be run by the State, the Governments then granting licences to private enterprise for auxiliary services. That was not the fact. In America wireless telegraphy was free to all. Any American subject might obtain a licence; erect a wireless station; conduct telegraph services, and the American naval stations could not compete with those services. When, in 1920, the Navy Department desired to use their stations for commercial services, the matter was dealt with by the Senate, and the Act which had been passed laid it down that

"the right to use such stations for any of the purposes named in this section shall terminate and cease as between any countries or localities or between any locality and privately-operated ships, whenever privately owned and operated stations are capable of meeting the normal communication requirements between such countries or localities or between any locality or privately owned ships and the Secretary of Commerce shall have notified the Secretary of the Navy thereof." That was a totally different position to that which one would gather from the paper. And what about France? The French Government decided that commercial wireless telegraphy could not be efficiently conducted by the Department of Posts and Telegraphs, and it had, therefore, entered into an agreement with the *Compagnie Générale de Télégraphie sans Fil*, under which the Company was to erect stations and to conduct all the commercial services of France, not only with foreign countries, but also with the French Colonies. Therefore, neither Government had adopted the "2,000 miles order." The author told them that the American Government stations communicating between Honolulu and Guam spanned a distance of 4,600 miles, and that the French Company were erecting stations to communicate with Saigon, Antananarivo and Brazzaville, which were at distances of 10,000, 9,000 and 6,000 kilometres respectively. He was surprised, too, that the author had not mentioned the telegraph services being conducted by the Radio Corporation of America between Honolulu and Japan—3,375 nautical miles. In speaking of the German stations erected before the war, the author said it was believed that it was doubtful if any successful signals were exchanged with Windhuk, which was 5,000 miles from the Nauen station in Germany. He did not know with whom the author meant there existed that doubt. He thought the Services would tell him that when the Germans required, at the outbreak of war, to communicate with Windhuk and their other far-distant stations, they had been so successful in doing so that even prior to our having knowledge in this country that war had been declared, communications had been received by each of their colonial stations advising all their Mercantile Marine of the declaration of war; and in consequence of those messages having been so efficiently received the Germans were able to save practically the whole of their mercantile marine from capture. Speaking, by the way, of the German chain, the author stated that it comprised three stations in Africa, one in Java and one in Yap, and that those stations were lost during the war. He was sure the author would pardon him if he reminded him that Java was in the Dutch East Indies and that the station there was not in existence prior to the war. It had only been constructed since, and belonged to Holland, not to Germany. The Telefunken Company were building a

station in Holland in order to communicate with Java. It would be recognised from the facts he had just given that foreign Governments were not of the opinion that a service should be limited to the "2,000 miles order." None of the principal wireless telegraph companies of the world were of that opinion either, and it must be borne in mind that it was the commercial companies who had the assistance of the ablest experts and those who alone had had practical experience in long-distance commercial services. The Radio Corporation of America (with which was associated the General Electric Co., of Schenectady, the Westinghouse Company, the Western Electric Company, the Thomson Houston Company and the Bell Telephone Company), the Telefunken Company of Germany (which was connected with and had the assistance of the A.E.G. and Siemens and Halske) the Compagnie Générale de Télégraphie sans fil of Paris (which was connected with the big French electrical industries), and the Marconi Company, with all its associated companies, were all convinced of the efficiency and economy of services over long distances. So much was that their opinion that they had joined together in the construction of stations in South America to conduct direct services with the United States, France, Germany and, if the necessary conditions were forthcoming in this country, with England. Direct services with Peking and Japan were also under consideration. The Japanese were very satisfied with their experience in long-distance telegraph services and were desirous of joining with the four great wireless companies in opening up certain long-distance commercial wireless telegraph services. The Commission, for which the author had been speaking, stood alone in the world in still upholding its recommendation in respect of stations of the "2,000 miles order." That was all he proposed to say in reply to the author's defence of the station of the "2,000 miles order." He would like, however, to ask indulgence for a few moments longer to reply to what the author had said upon the subject of patents. Whilst he quite agreed that the patent question was very much allied to the question of the Imperial chain of stations, nevertheless, he felt that the author had been badly advised in dealing with that subject in the way he had in his paper, for it seemed to him to make a most damaging attack upon a great British enterprise which it was his duty to defend. The author said: "I am instructed that the rights of the Meissner patent have been acquired by the Marconi Company and that user of it has been paid for by the Crown in the £590,000 awarded to the Company by Mr. Justice Lawrence." He noticed that the author used the words "I am instructed," and personally he was quite convinced that Dr. Eccles would not have said that of his own accord, for he did not believe for one moment that the author was expressing his own opinion. It was, nevertheless, a very

serious statement to have made in his paper, bearing in mind that he had been listened to by a very important and influential audience and that his paper would probably go forth to the world and be published broadcast. It was material to the Marconi Company, and also to prevent the Dominions being misled, that he should dispose of that extraordinary contention. First of all, he would like to ask the author if he had been instructed that in September last the Post Office had been given notice of six patents which were being infringed at the Leafeld Station—a matter which was still "receiving consideration." It was difficult to conceive that anybody could hold the view that because the Marconi Company was awarded damages for a breach of contract, on that account, they should have rights—what rights nobody had yet attempted to define—to use the Marconi Company's patents—what patents or for how long equally remained undefined. He might say, however, that so far no such contention had been put forward formally.

Mr. Godfrey Isaacs then proceeded to read the observations made by Mr. Justice Lawrence before handing down his Award, and the terms of the actual Award, in which he stated there was not a word which gave to the Post Office any rights of the kind claimed. It did nothing more than define the amount of damages they must pay for breach of a contract. After quoting the opinion of two of the most eminent King's Counsel, whose opinion the Marconi Company sought directly it was verbally stated to them that such a contention might be raised, Mr. Godfrey Isaacs said that he was quite satisfied to leave it to those present to form their own opinion upon the statement of the facts as to whether damages for breach of contract could possibly provide anybody with right under an agreement, which agreement had been rescinded years ago. The author stated, quite rightly, that the Government had power to use any patents it pleased, but it must be remembered that the very Act which gave the Government that power provided that the subject should have the same recourse against the Crown as it had against the individual, and that if terms could not be arrived at by agreement one had the right of recourse to the Courts. The Meissner patent and all other German, French, American and Marconi patents were the property of the Marconi Company in the whole of the British Empire, and wherever those patents were used, whether it be at Leafeld or across the oceans, fair and proper remuneration according to the value of those patents, must be paid. We were not Bolsheviks in this country, and private property could not be seized without due compensation being paid. If that order were ever to change there would be an end to all private enterprise and the ruin that Communism had brought about elsewhere would reign in this country.

LIEUT.-COLONEL W. A. J. O'MEARA, R.E., C.M.G., M.I.E.E., said he had been much interested to learn of the progress that had taken place on the technical side of wireless telegraphy and its proposed application in connexion with the Imperial Wireless Communication scheme, but he confessed that he was disappointed at not having heard anything connected with the progress of the Imperial organisation to carry on that scheme. It was no good projecting schemes unless at the same time an organisation was formed to carry them on. He had learned during the discussion that the Empire was not in accord on the Imperial communication scheme, the reason for which he made bold to say was because the proposed organisation for conducting the service was not suitable for dealing with it. He gathered that Lord Milner's Committee was simply an Advisory Committee which might be called in when it was wanted, and was not used when it was not wanted. When its advice was likely to be acceptable it might be called in; when not it would not be appealed to. That he considered a most unsatisfactory state of affairs if it was desired that progress should be made. The scheme could not be looked upon from the purely parochial point of view that it was a Post Office matter, and he feared the reason that no progress had been made was due to that cause. In his opinion the Post Office organisation was not a suitable one for dealing with such a vast scheme. It was an Empire scheme which required an Empire organisation to carry it on, containing representatives from the Dominions and Colonies affected. The author had given particulars of how the scheme could be carried on and of the progress being made in the Signal Corps and in the Royal Navy. Personally he suggested that the scheme primarily was a strategic one and that it should be run by the Army, the Navy and the Air Force, and that they had technical and administrative personnel competent to deal with it. In his opinion the Post Office had too much on its hands already. He did not know whether any minute had been sent to the Postmaster General pointing out what the recommendations of the Select Committee on the Telephone Service relating to the re-organisation of the Post Office meant, but if he read the remarks of the Postmaster General in the House of Commons of the previous night correctly he (the Postmaster General) had misrepresented the recommendations of that Committee. He mentioned that because wireless was entirely a scientific matter, and if the organisation of the Post Office could not deal with the Report of the Select Committee in a scientific spirit and way, that alone condemned the Post Office organisation. Wireless was not ordinary wire telegraphy; it dealt with an entirely different set of phenomena, and required differently educated and trained people to handle the service. He emphasised that if the scheme was to be

carried through an Imperial organisation was necessary.

THE RIGHT HON. SIR HENRY NORMAN, Bt., M.P., thought the Chairman had called upon him because he knew that he would be perfectly safe in trusting him to switch off the discussion from the atmosphere of acute controversy into which it had been plunged to one more in accord with the scientific traditions of the ancient hall in which the meeting was being held. It afforded him the greatest pleasure to move that the thanks of the meeting be accorded to the author for his learned and most interesting paper. He was personally qualified to move the resolution, because few persons, if any, were more able to appreciate than he the public services which Dr. Eccles had rendered. He had had the privilege and great advantage of working with him for a considerable period of time in connection with many subjects and had learned that he was a man of profound knowledge, which was only exceeded by one other quality, namely, his modesty and his willingness to put his great learning under all circumstances at the service of those who were desirous of knowing and were less gifted than himself. Nothing was more discussed at the present day than the subject of wireless telegraphy. It was impossible to open a paper without seeing fresh arguments about it. It was impossible to open a technical journal without running head first against the age long controversy as to who was the original inventor of wireless telegraphy. He had no hesitation in saying that, in the opinion of all who knew, an opinion which history would certainly confirm, no man had rendered greater services in transmuting what was originally a beautiful and academic laboratory experiment into a great service for the inestimable benefit of mankind than Senator Marconi. Wireless had made progress of extraordinary speed. It seemed to him as if it was only yesterday that he succeeded in passing a wireless telegraphic signal from one end of a bench in his workshop to the other, and yet at the present time signals could be sent from this country to Australia; and he remembered how proud he was when he first succeeded in hearing the signals from Clifden, which was at that time the great wireless station. He also recollected during the comparatively early days of the war, when he was a scientific liaison officer between England and France, receiving an urgent message from London to supply the English services with 24 French valves, similar to the ones that the author had exhibited, the request being accompanied by a private letter from the authority instructing him if possible to buy 24 valves; if they could not be bought to beg them, if they could not be begged to borrow them, and if they could not be borrowed to steal them. When it was thought impossible that wireless could go any further, suddenly the announcement was made

in the House of Commons that the country was to be presented with a new development in the shape of broadcasting. Before long every household would be able to listen to music and songs and instructive entertainments by Sir Harry Lauder and Mr. George Robey, and to a sermon on Sunday mornings, while stories would be told to the children at bedtime. In fact it was highly probable that in the future the telephone would be carried to the side of the cradle, and the youngest member of the family would be hushed to sleep by a lullaby sung by Miss Clara Butt! While the members of the House of Commons were a little amused and somewhat sceptical at his remark that they would address their constituents at the next election—if it was postponed for some time—by wireless telephony, they had overlooked the fact that if they addressed their constituents by wireless they would at any rate be relieved from the attention of hecklers! It afforded him the greatest possible pleasure to move the resolution.

SIR THOMAS J. BENNETT, C.I.E., M.P., in seconding the motion, desired to couple with it an expression of thanks to Lord Burnham for his kindness in presiding over the meeting. The way in which the Chairman filled every post he was called upon to occupy was a marvel almost as marvellous as wireless. There was no man in the public life of England who "moved up to his bit" as Lord Burnham did, and he thought of suggesting to the Secretary that his Lordship should be asked to preside over the meetings of the Society more often than he had done in the past.

The resolution of thanks to Dr. Eccles for his valuable paper and to Lord Burnham for presiding was then put and carried unanimously.

DR. W. H. ECCLES after thanking those present on behalf of Lord Burnham and himself, for the very cordial manner in which the resolution had been passed, said the present was not the time nor the Royal Society of Arts the place to reply in full to the comments that had been made by Mr. Godfrey Isaacs. He would like to say, in reply to Signor Marconi, that a great deal of controversy about the relative strength of signals still occurred because such poor methods of measurement were available. He had recently received from the Naval Laboratory at Washington a chart of measurements in which the strength of signals varied more than 200-fold from 10 o'clock on one morning to 10 o'clock the next morning; many who had been connected with wireless telegraphy from the beginning did not realise those huge variations. He thought that Senator Marconi himself had not perhaps measured them up carefully hitherto. With regard to Mr. Godfrey Isaacs's comments, he felt he would not be thought unfair if he said that Mr. Godfrey Isaacs's statement was an *ex parte* one. The suggestion that the

Dominions and India had withdrawn from participation in the chain scheme was new to him, and made him think that the wish was parent to the thought. The suggestion that had been made that the paper had been prompted by someone within the Government was very wide of the mark. As a matter of fact he had rather feared that it might cause offence within Government circles for him to have accepted the invitation of the Royal Society of Arts without express permission from his Chairman. The naval stations of America that had been mentioned closed down their commercial traffic as soon as other facilities were provided, but he thought commercial traffic was still proceeding on the Pacific coast at the naval stations between California and Alaska. The statements that had been made about the French Government and its relations with the *Compagnie Générale* were quite correct, and he did not think anything he had said was in conflict with them. He did not know, however, that any official statement had been made on the part of the French Government that the Bordeaux station and the Lyons station belonging to the French Post Office were to be handed over to a commercial company or to be closed down for commercial work. On the contrary, to the best of his information they had settled down permanently to commercial work. The statement of Mr. Isaacs that Windhuk and other stations received signals which enabled Germany to save much of her shipping reminded him of the old confusion that arose about communication between two stations to and fro and reception at one. Any installation in a ship at sea could receive from the great station at Nauen, but that was not what he meant when he said that communication was not established between Windhuk and Nauen. No signals from Windhuk were ever received efficiently at Nauen. In that connection he spoke with the authority of the engineers of those stations, who had published in full an account of their work before the war and during the war. He was sure he would be excused from comment at the moment on matters regarding patents and the Lawrence Judgment. They were legal rather than technical matters, and the opinions he had given in the paper were the considered views of the highest authorities in the land on the legal side, which he believed had been in the possession of Mr. Godfrey Isaacs for many months.

The meeting then terminated.

GAMBIER* PLANTATION.

Gambier is planted from seeds in nurseries until the plants are 4 to 5 inches high when they are planted out 6 to 10 feet apart.

A gambier estate is generally spread over a large area, in which there are patches of

*Extracted from "Notes on Sarawak Trade," published by the Committee for Agricultural and Forest Exhibits, Malaya-Borneo Exhibition.

planted ground and the estate usually aggregates 70,000 bushes; in addition to the planted area large timber reserves are necessary to supply firewood.

Gardens are weeded twice a year by hand until the young plants are two years old, after which period they are weeded by hoe.

Gambier is prepared from the leaves and young shoots of the bush, which are gathered every six months after the second year. The 70,000 bushes are attended to by seven men, including those engaged in the preparation of the gambier; of these seven men, two are employed weeding, two gathering, one procuring firewood, one in charge of the cooking process and one general coolie; the work is extremely hard and scale of wages low, especially when the gambier market is low, when it is customary to reduce wages.

If a plantation is not worked regularly the plants are ruined, so gathering takes place even if the price of gambier is so low that the owner incurs a loss on the manufacture. When gathering does not take place regularly the leaves turn red, the young shoots harden and production of young shoots ceases.

Cutting the leaves commences at daylight and continues until 8 o'clock, the weeders assisting the gatherers in bringing the leaves to the factory; at 10 o'clock the gatherers have to go out for leaves for the afternoon cooking, returning about 1 p.m. These gatherers do not assist in the cooking process although they cut the leaves with choppers to prepare for cooking. About 3½ piculs of leaves, etc., are gathered at one time.

Leaves on the main stem are taken first, then the leaves and shoots of the side branches, leaving the upright shoots to produce future supplies.

Harvesting from each takes place once in six months, the gatherers moving from patch to patch of planted area over the whole Estate; some of these gardens are often two miles from the factory.

FACTORY.

The gathered leaves and shoots are taken to the factory, chopped up, and put into a large copper, which has sides built up with wood, set over a large furnace fed by firewood.

The cuttings are boiled for three hours, being continually turned over with a special wooden instrument having five long prongs; when cooked they are removed by means of a large three-pronged fork and put into a trough (jalor) above, which is set at an incline towards the cooking copper; after the larger leaves have thus been removed the smaller broken pieces are strained by means of a rattan strainer. The cooked leaves, etc., are washed with cold water; the first washings, still of a dark brown colour, run back into the cooking apparatus; the weaker washings are led off through a small trough into a receptacle fixed next to the main copper. These weak washings are transferred to

the main copper for the next washing, the new leaves, etc., being added to it.

The liquid in the main copper is now cooked for a further two hours, after which it is removed to small tubs to cool.

If this liquid is left to cool the gambier will not solidify; in order to attain this result a short stick is inserted into the tub at an angle and coolies immerse their hands in the warm liquid and rub up and down the stick with a spiral motion until the colour of the liquid becomes lighter. During this process it thickens; after the liquid has been "worked" for about 15 minutes it is left, and when quite cold is of the consistency of cheese.

When it is quite cool the gambier is removed from the tubs and cut up into sections after which it is dried in the sun for one day and then placed in the rafters of the factory for smoking.

CUBE GAMBIER.

After cooking, the liquid is put into tubs as before, and about 4 tahils of rice bran, which has previously been fried and passed through a sieve, is added; this mixture is "worked" as before and just before becoming solid it is poured into a mould made of wood. The mould is set on a mat and on all inside casings of it are lines to mark the moulded gambier ready for cutting. When the gambier is set, the side of the mould is opened and the block is cut up into cubes by means of thread.

The wet cubes are placed in a bamboo tray and left to dry for one day, after which they are placed in the rafters of the factory to be smoked; this process takes about nine days.

THE NIPA PALM.*

This palm grows in abundance in the mud on the banks of all the rivers of Sarawak, near the coast. It differs from other palms in that it has no trunk, being merely a collection of leaf stems proceeding from a central "stem."

Amongst its many uses the following are perhaps of interest. From the "stem" salt is produced. It is also used as floats of timber rafts; native fireplaces in cases of emergency. When found floating, rotten, in the stream it is collected by natives, dried, made into a fine powder, and used for the treatment of wounds; it is said to be very efficacious. The skin inside the base of the leaf stems is used extensively for making boat balers. The leaf stem itself is sometimes used for flooring and attap ribs. The heart is eaten as a vegetable.

The mature leaf is made into atap for roofing houses and generally as wrappers (tampin), especially for lime and sago.

The leaf ribs are used for making brooms, stands for cooking pots, in the manufacture of atap, baskets, etc., and also the split ribs are

*Extracted from "Notes on Sarawak Trade," published by the Committee for Agricultural and Forest Exhibits, Malaya-Borneo Exhibition.

frequently used in the place of string or rattan. The flower is made into a preserve. The fruit, when young, is also made into a preserve and when old is used instead of betel nut. The husks of the fruit are used for brushes. From the sap from the stem of the flower or fruit sugar and vinegar are obtained.

NIPA SUGAR.

A suitable site having been chosen the worker builds a small house (langko) and proceeds to clear the area he intends to work, cutting away the old dead branches and undergrowth.

At the same time he prepares two fireplaces upon which are placed two large cauldrons, and collects firewood; then he prepares 200/300 lengths of bamboo about 1 foot long and 3 ins. diameter, which, together with the knapsack, knife, parang, and axe, complete his outfit.

The first two days are spent in peeling the outer skins from the flower stalks and bending them until they droop, the flower is then cut off and the bamboo placed under the end of the stalk to collect the sap which exudes therefrom; this is done in the evening and the bamboos containing the sap are collected early the next morning—sometimes the bamboos are completely filled but generally they are not more than half full of sap.

While collecting, the worker cuts a thin slice from the end of the stalk to prevent it from drying up; during the day the sap runs to waste, interference from bees, hornets and monkeys making it impossible to work.

In the evening the bamboos are set as before and another thin slice cut from the end of the stalk. This process continues about 4 months, from August to December, until it is no longer possible to work the stalk.

The bending of the fruit stalk is considerably more difficult than in the case of the flower stalk, the process occupying about 1½ months instead of two days. The yield and quality are the same in both cases, but the fact that so few workers understand the latter method explains the reduction in output from January to August.

It is estimated that two-thirds of the total output is produced in the 5 months when flower stalks are worked.

PREPARATION.

The bamboos containing the sap are collected in the early morning and carried back to the worker's house in his knapsack at about 9 a.m.

The sap contained in the bamboos is poured through a strainer into the cauldrons, where it is cooked until it boils; then, to prevent waste by boiling over, a circlet of bark is fitted around the inside of the cauldron. This circlet is about 3 feet high.

The empty bamboos are placed upside down on a platform above the fire to dry so that they shall remain sweet and clean.

After about 5 hours the sugar is cooked and the cauldron removed and placed in a hole in

the ground, prepared to receive it: it is then stirred for about an hour with a long handled ladle made of cocoanut shell and poured off into tins or jars when it is ready for market.

Two hundred bamboos of sap will produce 3 gallons of sugar the present price of which is \$1.20 per 4 gallon tin.

NIPA VINEGAR.

The froth from the boiling sugar put into jars and kept for 2 or 3 days becomes vinegar.

NIPA SALT.

This is made from the old stems of the palm. These are cut down and thrown on to a wood fire and burnt till nothing but ashes remains.

The ashes are collected and put into deep baskets and set over an empty boat which has previously been divided into separate watertight spaces. Water is then poured on to the ashes and, filtering through them, drops into the spaces prepared for its reception. The filtering process is continued till the resulting mixture is of such a density that the fruits of the rattan will float on the surface.

The mixture is now poured into vessels made from the sheath of the nibong palm and boiled. A narrow trench serves as a fireplace and the cooking pots which are about 1' x 4" are laid cross-wise and a wood fire made underneath. As the water boils away leaving a deposit of salt on the sides of the vessel, more of the mixture is added till finally the whole contents become solidified. The cooking process generally lasts for about 6 or 7 hours. The contents of one vessel are worth at present prices about 25 cents.

PRODUCTION OF PINE TIMBER IN SOUTH-WESTERN FRANCE.

One of the most important sources of wealth in south-western France, ranking next to its vineyards and its naval stores, is the timber produced from the maritime pine. The following table shows the forest area of the Departments in south-western France and the area of maritime pine found in these Departments:—

Departments.	Total area.	Area covered by forest.	Area of maritime pine.
	Hectares.	Hectares.	Hectares.
Charente-Inférieure	682,556	81,670	11,100
Dordogne ...	918,255	255,778	8,300
Lot	521,174	108,616	900
Gironde ...	997,988	461,915	299,200
Lot-et-Garonne	536,011	81,278	39,500
Landes	932,277	516,608	462,400
Total ...	4,588,261	1,505,865	821,400

Hectare=2.471 acres.

It will be seen that of the total forest area of 1,505,865 hectares, 821,400 hectares, or about 55 per cent., is covered with maritime pine.

The various kinds of timber produced from the maritime pine, and the average annual production of each, are as follows:—

	Cubic Metres.
Carpenters' and joiners' timber and wood paving blocks	300,000
Flooring planks	250,000
Planking for export to Spain	150,000
Packing-case timber	215,000
Railway ties	210,000

These figures show a total annual production of 1,125,000 cubic metres of sawn timber from the maritime pine. In addition, the maritime pine produces an annual yield of other products as follows:—Mine supports, 773,000 cubic metres, consisting of 750,000 cubic metres of peeled pit props and 23,000 cubic metres of unpeeled pit props; telephone and telegraph poles, 9,000 cubic metres; firewood, 364,000 cubic metres. There is, therefore, a total yield of 2,578,000 cubic metres of timber annually from the maritime pine of south-western France, which represents an average annual yield of 3.14 cubic metres per hectare.

According to a report by the United States Vice-Consul at Bordeaux, unpeeled mine supports form one of the principal exports from the ports of Bordeaux and Bayonne to Great Britain, where they are used in the coal mines. The average annual exports of unpeeled mine supports to Great Britain for the years from 1914 to 1920 amounted to 640,000 metric tons. In 1920 alone exports of mine supports to Great Britain amounted to 776,000 metric tons, valued at £2,800,000.

Peeled mine supports are used principally in France's own coal mines, particularly in the Departments of the Tarn and Aveyron. Most of these peeled mine supports are furnished by the Departments of the Gironde, Landes, and Lot-et-Garonne, but the two Departments of Lot and Dordogne, which are nearer to the mines, produce peeled pit props in smaller quantities. Owing to the rise in railway rates, however, a production in the three Departments first mentioned, which are at a comparatively greater distance from the French mines, has lost its stimulus and has fallen from 4,000 tons in 1914 to 1,000 tons.

THE SEAWEED INDUSTRY IN HOLLAND.

The harvesting of seaweed and its preparation for commercial use form an industry which has attained importance in the Amsterdam district during the last few years, according to a report by the United States Consul in that city.

At the northern extremity of the Zuider Zee and in its easterly extension, called the Wadden Zee, between the mainland and the chain of islands extending towards the German coast, seaweed grows abundantly in an area some

three miles in circumference. The soil of that place happens to be peculiarly adapted to seaweed, which can thrive only in soft and somewhat muddy ground.

At the locality in question, the water is relatively shallow, and at ordinary high tide the bed out of which grows the seaweed is not more than five feet under the surface.

In order to obtain the best quality for commercial use, the seaweed is mown from June to August. It is mown with scythes, as it grows straight, and its top nearly reaches the surface of the water. The mowers work when the tide is low, standing in the water, but clothed in a water-tight garment reaching to the shoulders. Formerly one scythe was used at a time, but now several are fixed to a line, which the workers draw to and fro like a saw above the base of the weed. The product is spread out on adjacent fields to wither in the sun. When it becomes black, it is placed in ditches to soak in water. The fresher the water the blacker the weed turns, and the blacker it is the higher becomes its price. After a few days in the ditch the weed is again spread on the field, and when thoroughly dry is taken into warehouses, where it is made up by means of a press into bales of about 100 pounds each, ready for market. Seaweed harvested in the late autumn is left in the ditch all winter.

Formerly, no restrictions controlled the mowing and marketing of the seaweed, which resulted in over-production and a decline in price, which made the business unprofitable. The Government, therefore, decided to lease the weed lawns to the highest bidder. Two wholesale seaweed merchants secured the lease at an annual rate of 30,000 florins (florin = 1s. 8d. at normal exchange). However, this did not work satisfactorily, the result being that the municipality of the island of Wieringen was granted the right to deal with the seaweed, and this arrangement has proved satisfactory to all concerned. The municipality fixes the price of the weed, which is from 8 to 15 florins per 100 kilos.

There is also a "fished" seaweed, which is said to be much inferior to the mown. It is caught along the dykes by hooks. Its price is usually 3 or 4 florins per 100 kilos.

The fully prepared seaweed is chiefly used, as filling for mattresses and the like. But during the past 20 years many experiments with seaweed have been made in the Netherlands, during which, it is stated, some fine qualities of gelatin were produced.

The exports of seaweed from the Amsterdam district aggregate from 2,000 to 3,000 tons annually, going chiefly to Belgium, England and France, with occasional shipments to the United States. The total annual product of the weed lawns is not stated, but it is understood that much the larger part is used in the home trade. The industry employs several hundred people.

GENERAL NOTES.

TEA OIL PRODUCTION IN CHINA.—China is the only country which produces tea oil in large quantities, according to a statement published by the United States Bureau of Foreign and Domestic Commerce. Japan has a small production, and French Indo-China and India make from the *Camellia drupifera* an oil that is used by the natives as a medicine. The largest producing district in China is in eastern Kwangsi and southern Hunan. Wuchow, near the Kwangsi-Kwangtung boundary, is the principal collecting and exporting centre of the country and annually accounts for more than half the total exports from China. Hankow is the next largest shipping port, the oil being collected from Hunan, Hupeh, and especially from Szechwan. Kiangsi Province is a larger producer of tea oil, but its exports are small, as most of the output is consumed in the Province. Canton, Foochow, and Changsha all make fairly important shipments, and small quantities are exported from Shanghai, Ningpo, Wuchow, Amoy, Swatow, Kowloon, and Nanning. Santuao had a share in the export trade until 1919, when shipments stopped altogether.

MARBLE IN THE ISLE OF PINES.—A large deposit of marble is being successfully developed near Nueva Gerona, Isle of Pines, by a Cuban company, recently put under American management, writes the United States Consul at Nueva Gerona. As a result of the recent installation of modern appliances, it is expected that when the plant is in full working order over 3,500 square yards per month will be produced. Hitherto the marble has all been marketed in Habana, but the new management will endeavour to place future production on the market in the United States.

KAOLIN DEPOSITS IN FINLAND.—Investigations concerning the extent of the kaolin deposits in Puolanka (Finland) were carried on during the summer of 1921, writes the United States Consul at Helsingfors, with apparently very favourable results. It has been ascertained that there are at least 10,000 tons, and a calculated probability of more than 500,000 tons. Kaolin has been found also in four different places in Pihlajavaara. The deposits are 4 to 6 metres deep; in some places the stratification is over 10 metres deep, and it has been noticed that the deeper stratification furnishes the better kaolin. According to German experts, this kaolin is of excellent quality, clearer and better than elsewhere in Europe; and the china made from it is entirely white. Besides kaolin, red and yellow ochres have also been found at Pihlajavaara; but, although of good quality, they will probably be of little economic importance owing to the cheapness of their products.

MEETING OF THE SOCIETY.

INDIAN SECTION.

FRIDAY, JUNE 23 (at 4.30 p.m.)—F. W. Woods, C.I.E., late Chief Engineer, Irrigation Department, Punjab, "Irrigation Enterprise in India." **LORD LAMINGTON, G.C.M.G., G.C.I.E., Governor of Bombay, 1903-7, in the chair.**

MEETINGS OF OTHER SOCIETIES FOR THE ENSUING WEEK.

- MONDAY, JUNE 12.** University of London, at the Royal Society of Medicine, 1, Wimpole Street, W., 5 p.m. Prof. Dr. A. A. H. Van den Bergh, "Injurious Agents and Growth." Royal Institution, Albemarle Street, W., 5 p.m. General Meeting.
- Engineers, Society of, at the Geological Society, Burlington House, Piccadilly, W., 5.30 p.m. Two papers by Dr. H. Chattey and Mr. A. S. E. Ackermann, "The Physical Properties of Clay." Victoria Institute, Central Buildings, Westminster, S.W., 4.30 p.m. Miss A. M. Hodgkin, "The Witness of Archaeology to the Bible." Geographical Society, 135, New Bond Street, W., 8.30 p.m.
- TUESDAY, JUNE 13.** University of London, at Gray's Inn Hall, W.F., 4.45 p.m. The Hon. J. M. Beck, "The Nature of American Institutions and their Bearing on International Relations." (Lecture I.) Anthropological Institute, 50, Great Russell Street, W.C., 8.15 p.m. Professors G. E. Smith and J. I. Hunter, "A Re-construction of the Pittdown Skull." Photographic Society, 35, Russell Square, W.C., 7 p.m. Mr. F. T. Usher, "Matt Surface Plates." Colonial Institute, Hotel Victoria, Northumberland Avenue, W.C., 8.30 p.m. The Hon. W. G. Ormsby-Gore, "British West Indies." Anglo-French Society, Scala House, Tottenham Street, W., 6.15 p.m. M. Maurice Thériy, "Le Théâtre de Brioux." Literature, Royal Society of, 2, Bloomsbury Square, W.C., 5 p.m. Prof. Paul de Reul, "The Centenary of Shelley." Zoological Society, Regent's Park, N.W., 5.30 p.m. 1. The Secretary, on "The Council's Scheme to establish an Aquarium in the Society's Gardens." 2. Miss Joan B. Proctor, "A Study of the Tortoise *Testudo heraldi*, Blgr., and the Morphogeny of the Chelonian Carapace." 3. Mr. J. T. Carter, "A Microscopical Examination of the teeth of the Primates." 4. Mr. H. G. Jackson, "A Revision of the Isopod Genus *Ligia* (Fabricius)." 5. Mr. W. R. B. Oliver, "A Review of the Cetacea of the New Zealand Seas." 6. Prof. Wood Jones, "The Dental Characters of certain Australian Rats." Asiatic Society, 74, Grosvenor Street, W., 4.30 p.m. Brig-Gen. Sir Percy Sykes, "The Achaemenian Dynasty."
- WEDNESDAY, JUNE 14.** Microscopical Society, 20, Hanover Square, W., 8 p.m. 1. Mr. J. Strachan, "The Microscope in Paper Making." 2. Mr. A. C. Chapman, "The Use of the Microscope in the Brewing Industry." Geological Society, Burlington House, Piccadilly, W., 5.30 p.m. British Academy, at the Royal Society, Burlington House, Piccadilly, W., 5 p.m. Dr. C. Singer, "Leonardo da Vinci as an Anatomist, with special reference to his Medieval Sources."
- THURSDAY, JUNE 15.** Aeronautical Society, at the Royal Society of Arts, John Street, Adelphi, W.C., 5.30 p.m. Lt.-Col. A. Ogilvie, "Some Aspects of Aeronautical Research." (Wilbur Wright Memorial Lecture.) University of London, at King's College for Women, Campden Hill Road, W., 4.30 p.m. Prof. V. H. Mottram, "Metabolism of Fat and Allied Substances." (Lecture VIII.) NOTICES.

NEXT WEEK.

FRIDAY, JUNE 23rd, at 4.30 p.m. (Indian Section.) F. W. WOODS, C.I.E., late Chief Engineer, Irrigation Department, Punjab, "Irrigation Enterprise in India." LORD LAMINGTON, G.C.M.G., G.C.I.E., Governor of Bombay, 1903-7, in the chair.

ANNUAL GENERAL MEETING.

The Council hereby give notice that the One hundred-and-Sixty Eighth Annual General Meeting, for the purpose of receiving the Council's Report and the Financial Statement for 1921, and also for the election of Officers and new Fellows, will be held, in accordance with the By-laws, on Wednesday, June 28th, at 4 p.m.

(By order of the Council)

GEORGE KENNETH MENZIES,

Secretary.

SOCIETY'S ALBERT MEDAL.

The Albert Medal of the Society for the current year has been awarded by the Council, with the approval of his Royal Highness the President, to Sir Dugald Clerk, K.B.E., D.Sc., LL.D., F.R.S., in recognition of his important contributions, both theoretical and practical, to the development of the internal combustion engine, which in its latter forms has rendered aerial navigation possible, and is also extensively employed in the motor car, and in the submarine and for many other purposes.

DOMINIONS AND COLONIES SECTION.

FRIDAY, JUNE 9th, 1922; The Right Hon. Sir Frederick D. Lugard, G.C.M.G., C.B., D.S.O., in the chair.

A paper on "Tanganyika Territory (formerly German East Africa)" was read by Major Sir Humphrey Leggett, D.S.O., R.E.

The paper and discussion will be published in a subsequent number of the *Journal*.

PROCEEDINGS OF THE SOCIETY.

INDIAN SECTION.

FRIDAY, APRIL 28TH, 1922.

SIR WILLIAM GILLAN, K.C.S.I., LL.B., in the chair.

The paper read was :—

THE NEED FOR AN ALL-INDIA GAUGE POLICY.

By FREDERICK GEORGE ROYAL-DAWSON, M.Inst. C.E.

INTRODUCTION.

Ten years ago a paper on "Indian Railways" was read before this Society by the late Mr. Neville Priestley, a traffic officer who was at one time Secretary to the Indian Railway Board, and who subsequently became associated with the South Indian Railway, first as General Manager in India and finally as managing Director in London. Mr. Priestley's paper was taken up mainly with the financial side of the subject, the gauge question being only incidentally touched on as influenced by financial considerations in the past. Mr. Priestley's object was to show that an extensive programme of railway construction was needed, especially in the form of light feeder lines, to open out and develop the country, but that Government methods were not conducive to the encouragement of private enterprise in this direction. In particular, he sought to show that the high capital cost of some railways had been due to the Government's insistence on too high a standard of construction, and this gave rise to a question

being asked in Parliament. But on this point he laboured under a misapprehension, for in the first place, not being an engineer, he perhaps did not realise that the first cost of a railway was influenced more by the nature of the country passed through than by any arbitrary standard of equipment or strength, and in the second place, his assumption as to the insistence of unnecessarily high standards was not in accordance with the declared policy of the Government, for although certain standards had been laid down for important lines, the Government had specially emphasised that such standards could be relaxed in cases where they were considered needlessly onerous. I may add that this attitude of "Gharib Parwar" or "Protector of the Poor" on the part of the Government in relation to light railways still holds good, only such standards of construction being insisted on as are dictated by common sense.

The methods of Government in dealing with railways have, however, been exposed to criticism in other directions. For this reason a Commission was appointed the year before last, under the chairmanship of Sir William Acworth, to consider the whole question of the administration of Indian Railways, including the general question of railway finance, also the knotty question of State versus company management, and the adequacy or otherwise of the system of administration and control by the Railway Board as at present constituted. Their report was published last year. Although the gauge question was not specifically included within the scope of their investigations they recommended (with one dissentient) that this question should be referred to a Committee of experts. This report is now under consideration.

In the meantime the Institution of Civil Engineers kindly gave me an opportunity, for which I am much indebted to them, to present a paper on the subject of the Gauge Problem for discussion in that Institution last November. This paper was somewhat technical in detail, but the discussion which it elicited was most valuable in that it indicated that the majority of those who expressed their views and who were competent to form a disinterested opinion on the question, agreed generally with my conclusions. By means of the discussion, also, I was placed in possession of the strongest potential arguments that could be brought forward by opposing interests

against my proposals and have thus had an opportunity to give these arguments full consideration when preparing the present paper. I am therefore in a position to assure this audience that the views which I am about to express, although not official, are backed by a large body of disinterested opinion, that such adverse criticism as they have already received has been considered and dealt with in this paper, also that they are not novel in character, but merely that they have been brought up to date. I may also add that they do not conflict with any Government Policy for the simple reason that the Government has no definite policy on the question at present.

BRIEF HISTORY.

It is necessary to begin the subject with a brief history of Indian Railways from the gauge point of view. Railway construction began in India about 70 years ago, that is in 1851, at a time when there were two legalised gauges on English railways, namely 7' as used on the Great Western and the Railways which it absorbed, and the 4' 8½" as used on all other lines. A passing reference should be made to the "Battle of the Gauges" which had been fought in England a few years before, when other gauges had also been in use. The net result of that battle was the public recognition of the fact that the inherent merits of any particular gauge were as nothing compared with the nuisance of a break of gauge, which prevented the rolling stock of one gauge being used on another. The first step towards the diminution of this nuisance was the legalising of the above-mentioned two gauges only, to the exclusion of all others. The second step came some years later when the Great Western, the sole representative of the 7' gauge, decided to abolish it in favour of the more general 4' 8½" in the interests of unification, thereby serving its own as well as the public convenience. For some years before the final abolition of the 7' gauge in 1892 the Great Western had adopted a mixed gauge on a portion of its main line, the track consisting of three rails, one rail being common to the two gauges. This was only the beginning of the end, for it was felt that the supposed advantages of a mixed gauge were not worth the complications involved in its maintenance as a permanent feature in dealing with a busy traffic. The use of the third rail,

however, showed that such a device could serve a useful purpose during the transition stage of a contemplated conversion.

America also had its "Battle of gauges," all lines being ultimately unified to the 4' 8½" or 4' 9" gauge in the interests of free interchange of traffic. This gauge has also become the main European Continental gauge.

With the above object lessons before them, the Government of India decided in 1851 that whatever gauge should be adopted in India, that gauge should be enforced for all railways, to avoid the evils of break of gauge. The actual gauge chosen as the legal standard was 5' 6", being intermediate between the two English gauges of that period. Incidentally it may be mentioned that this gauge was chosen to give, not greater capacity, but greater stability than the 4' 8½" gauge, as with carriage bodies of the same width there would be less lateral overhang in the rolling stock of the 5' 6" gauge.

Within the next fifteen or twenty years, about 5,000 miles of line, comprising the principal trunk routes leading from trade centres to ports, had been laid to this gauge by various companies with sterling capital on a 5% guarantee.

Unfortunately, these original lines were very costly in construction, not so much because the standard was unnecessarily high, but rather because the nature of the work was new, while the country was also difficult, involving the bridging of wide rivers and in some cases the traversing of steep mountainous tracts. Added to this initial handicap, the fall in the exchange value of the rupee resulted in these lines being a financial burden to the State. So that in 1869, when further railway extensions were desired for the development of the country, it was thought necessary to introduce a narrower gauge, namely the 3' 3½" or metre gauge, to be constructed by State agency in order to cheapen the first cost of construction. Thus for the first time were financial considerations allowed to interfere with the principle of uniformity, hitherto held to be of paramount importance.

An extensive programme was then carried out on the metre gauge. It is, however, due to the Government of that period to say that it was never intended that the metre should ever be anything but a supplementary gauge confined to particular areas. Mr.

Thornton, in defending the Government policy at a discussion in the Institution of Civil Engineers, in 1873, said, "In India there was no idea of letting the two gauges come into competition. There were not to be any standard gauge lines and metre gauge lines running from the same point in the same direction. Goods brought by railway to any station at which the break of gauge occurred, and intended to go on by railway, would have no choice but Hobson's. They must either proceed by the metre gauge or by the standard gauge, as the case might be, or they could not go on by railway at all, for there would be but one gauge to go on by." It is thus evident that whether the introduction of the metre gauge was right or wrong in principle, it was fully intended to restrict the activities of that gauge to definite regions. To perceive to what extent that idea has been departed from, it is only necessary to glance at a present-day railway map of India (vide Fig. 1.)

While the broad gauge still predominates the metre gauge crosses it at many points. The original metre gauge State lines were the Indus Valley and Punjab Northern (since converted to 5' 6" and merged in the North-Western Railway), the Rajputana-Malwa, still on the metre gauge but worked by the Bombay-Baroda broad gauge administration, the Tirhoot (now worked by the Bengal and North-Western metre gauge railway, which came later), and the Northern Bengal now forming the metre gauge section of the Eastern Bengal Railway.

Later on came the Southern Mahratta Company's Railway on a guarantee, and the Bengal and North-Western without guarantee. The former is now incorporated in and worked by the nucleus of the old broad gauge Madras Railway, while the Bengal and North-Western, though financially independent, has, from an early period, benefited from the fact that the lucrative Tirhoot Railway has been leased to it. In the meantime the Assam-Bengal and Burma Railways on the metre gauge came into being.

In the South of India the portion of the South Indian Railway between Erode and Negapatam was originally broad gauge, but is now metre.

Up to this stage the metre gauge areas were fairly well defined, but as the trend of affairs seemed uncertain, the Government in 1889 invited a Committee of railway

officers to enquire into the gauge question. This Committee recommended definite recognition of the 5' 6" gauge as the standard for India, and the rigid prohibition of any extension of the metre gauge, except in areas where it was already established. They further recommended that all feeder lines should be constructed on the same gauge as the parent line, but that anything of the nature of link connecting with broad gauge railways should be either constructed on the broad gauge, or so constructed as to be easily converted to it.

But these recommendations were not acted upon, for in the nineties the idea was started that all metre gauge railways should be connected with one another by metre gauge links. As a result of this heresy, the Cawnpore-Barhwal link, 80 miles long, was constructed by State agency across the broad gauge territory of the Oudh and Rohilkund Railway and actually alongside the broad gauge track of that railway between Cawnpore and Barhwal, to connect the Bengal and North-Western with the Rajputana-Malwa and Guzerat metre gauge systems, while with the idea of an ultimate north-and-south metre gauge connection, the Hyderabad-Godavari line, 391 miles long, was constructed over hitherto unoccupied territory, on the metre gauge, although connecting only with broad gauge railways at its two extremities.

Thus the recommendations of 1889 have been scattered to the winds, and there is now considerable interlacing of the gauges. Although the Guzerat and Jodhpore-Bikaner railways connecting with the Rajputana-Malwa system appear to be at present in purely metre gauge territory, the Karachi-Agra broad gauge project, which is likely to materialise in the not very remote future, involves the conversion of the greater part of the Jodhpore-Bikaner main line to broad gauge, besides the crossing, if not the conversion, of a portion of the Rajputana-Malwa. Similarly the north and south backbone line of the metre gauge section of the Eastern Bengal Railway is in process of being converted to broad gauge. These contemplated conversions serve as illustrations of a generally accepted, though not officially recognised, principle that arterial routes should preferably be on the broad gauge, and that, as a corollary, if a metre or other narrow gauge line occupies an alignment approximating that required for a contemplated arterial route, it is, in the

absence of specific legislation to the contrary, liable to be converted to broad gauge. As we have seen, some of the original metre gauge lines, such as the Indus Valley, being arterial in character, were subsequently converted to broad gauge.

A notable exception is the Rajputana-Malwa, which, before the construction of the Nagda-Muttra, was aligned on an arterial route between Delhi and Bombay, breaking gauge at Ahmedabad. It was at one time contemplated that this line would be ultimately converted, in anticipation of which it became the practice, when girders were due for renewal, to renew them up to broad gauge standard. Then came the construction of the Nagda-Muttra broad gauge railway, on an alternative alignment, through much more difficult and less productive country. This line, it is true, takes a heavy through traffic, but there is no apparent reason why, if the Rajputana-Malwa had been converted to broad gauge, as originally contemplated, it could not have dealt with this through traffic as well as its own. Of course, it may be argued that the Nagda-Muttra has served to open up new country, but, taking a wide view, the anomaly remains that, as between the two alternative routes the more important and less difficult terrain of the Rajputana-Malwa is served by a metre gauge railway, while the less important and more difficult terrain of the Nagda-Muttra is served by the broad gauge. The acquired importance of the latter is derived mainly from its through traffic, which has been more or less diverted from the Rajputana-Malwa and the Great Indian Peninsula routes between Delhi and Bombay.

The true explanation of this retention of the Rajputana-Malwa as a metre gauge line is, perhaps, to be found in the Cawnpore-Barhwal metre gauge link, already referred to, traversing the broad gauge zone of the Oudh and Rohilkund Railway, and actually laid alongside a broad gauge track, to connect the Rajputana-Malwa and Bengal and North Western systems.

Thus, we see how one departure from principle has led to another. The first departure from principle was the introduction of the metre gauge, on the grounds of cheapness of first cost, to supplement the standard gauge, in spite of the break of gauge involved thereby. The next de-

parture from principle was to connect two metre gauge systems with one another by a link traversing broad gauge territory, in order to increase the lead of purely metre gauge traffic, in full recognition of the fact that such a link represented redundant mileage, besides failing to obviate the necessity of transhipment points with the broad gauge in other directions.

It has been argued in defence of this particular example that the link was necessary in the public interests in order to develop the trade between the Sub-Himalayan region represented by the Bengal and North Western Railway on the one hand, and the Rajputana and Guzerat areas on the other. While fully recognising the force of the contention, a counter argument would be that there is no *a priori* reason why, on public grounds, the Bengal and North Western Railway should be connected with the ports of Guzerat by an unbroken gauge, while it has to break gauge with the more important ports of Calcutta, Bombay and Karachi, involving transhipment at about a dozen different points. In short, weighing the arguments against one another, the suggestion arises that, on general grounds, links of this nature are more conducive to the interests of the linked railways than to public interests as a whole, in the sense that, while they may create new traffic, they also tend to influence the natural trend of traffic. It must also be obvious that, if this linking up policy were carried out indefinitely, it would mean redundant mileage and consequent waste of capital everywhere, while it would not save the general public from the evils of break of gauge until every station in India had been served by both gauges, which is a *reductio ad absurdum*. Short of that consummation, the aggregate tonnage of transhipment would increase concurrently with the co-extensive increase in the mileage of the two gauges.

To those who argue that the introduction of the metre gauge in the seventies was an economic necessity, in order to increase the railway mileage of India at a lower first cost than would have been possible by the use of the standard 5' 6" gauge, the reply is that an even greater mileage could have been secured for the same money by a yet narrower gauge, such as 2' 6". It is significant that the existence of the metre gauge has not prevented the subsequent

genesis and growth of 2' 6" and 2' 0" gauges. To those who say that a narrower gauge would not have fulfilled the purpose for which the metre gauge was intended, the reply is that for thirty years after the metre gauge had been introduced, its average volume of traffic, measured by earnings in rupees per mile per week, had not attained the figures which several 2' 6" gauge lines can show at the present day. It should, however, be remarked that certain original metre gauge lines, such as the Indus Valley and Punjab Northern, were subsequently converted to broad gauge.

Assuming, however, that the metre gauge performed a useful function at a certain period in railway history, thus condoning the breach of the principle of uniformity for the time being, the fact remains that the metre gauge has grown to such an extent as to constitute at the present time a second main gauge. In other words, a dual gauge is now in full play. The present railway mileage according to gauges is, in round figures :—

Broad gauge	..	18,200 miles.
Metre gauge	..	15,300 ..
Narrow gauges	..	3,500 ..
Total		.. 37,000 ..

These figures represent route mileage only. For actual track mileage the figures for the broad gauge should be increased by about one-seventh to cover the double track portions on that gauge. With the exception of a small portion of the main line in Burma, and two short incidental "necks," seven and ten miles long respectively, in Upper India, the metre gauge is still practically all single track throughout India.

The outlay on the various gauges bears a close relation to their respective gross earnings, thereby indicating that the ultimate cost of a railway depends more on its volume of traffic than on its gauge. Thus, in 1883 the average cost per mile of a broad gauge line was 2.68 times that of the metre gauge, and the earnings 2.69 times as great. Again, in 1903, the average cost of the broad gauge was 2.49 times that of the metre, and the ratio of earnings also 2.49. Lastly, in 1920, the broad gauge cost per mile was 2.31 that of the metre gauge, and the ratio of earnings 2.35. It may be added that the average cost per mile of a narrow gauge line. (2' 6"

or 2') in the same year was .57, or rather more than half that of the metre gauge, while the earnings per mile were .40, or rather less than half.

I leave the narrow gauges out of the discussion for the present, because in the first place their combined mileage is comparatively small, and in the second place they carry their own limitations in regard to capacity and speed, so that they can never attain the status of main lines.

The questions at issue are—

- (1) is a perpetuation of the dual standard desirable in the public interests ?
- (2) If not, is alleviation of the evil financially practicable ?

I propose to answer the first question in the negative and the second in the affirmative.

EVILS OF BREAK OF GAUGE.

I will deal first with the evils of break of gauge, which are the inevitable results of the dual system.

Formerly it was assumed that the inconvenience of a break of gauge was confined to the actual handling charges of transshipment, the amount being equivalent to a few miles (say, 10 or 20 miles) of extra haulage. We now know by bitter experience that that is the least important factor of the situation. The main evil lies in the serious detention to rolling stock at every point of transshipment, amounting to at least a day, and sometimes several days, for every train concerned. This means incalculable delays in transit and the corresponding waste of locked-up capital, not only in rolling stock, but also in the goods carried. A certain agent of the Eastern Bengal Railway, which has both gauges in its system, estimated that from a railway point of view alone it would pay to spend Rs. 20 lakhs of capital outlay (equivalent to, say, £133,000—but this figure does not pretend to be exact), to avoid the transshipment of one broad gauge train a day. Again, every transshipment point is a fruitful source of damage and loss by theft of goods in transit, especially at important junctions, where transshipment on a large scale takes place. The Indian public, who have been brought up to regard this state of affairs as inevitable, do not appear to realise what a difference uniformity of gauge would make in the efficiency of railway transport and the development of trade generally. The evils of a break of gauge cannot be exaggerated, for, with

the co-expansion of the two gauges, they increase with the increase of tonnage transhipped.

As to whether wholesale transshipment at a big junction is preferable to transshipment at several scattered points for the same aggregate tonnage much depends on circumstances. In theory it may seem more convenient and economical to tranship 10,000 tons at one big junction instead of at a dozen scattered small ones. But in practice the worst congestions occur at big junctions, whereas if all main lines were of uniform gauge and the only transshipment points occurred at wayside stations where local feeder lines of a different gauge joined the main line, all transshipments would be of a local character and would be done by local station staffs, more or less under the observation of consignor or consignee, as the case might be, and, therefore, subject to less risk of mishandling or unaccountable delays or loss in transit. So far as the consignor or consignee is concerned, therefore, there is no doubt that the least objectionable position for a transshipment is near the beginning or end of a journey, as in the case of a wayside station, served by a local feeder line, the latter being merely a substitute for local road transport.

From the administrative point of view the supply and movement of wagons is the chief difficulty, especially as between two administrations where exact synchronisation of supply at transshipment points is almost impossible of attainment.

Even railways which have the two gauges under one administration (such as the Bombay-Baroda, the South Indian and the Eastern Bengal), and which should, therefore, be able to insure the co-operation of both gauges in the punctual and adequate supply of wagons at transshipment points, find this process a perpetual source of anxiety and liable to break-downs at critical moments. The following extract from a report by Mr. Waring, who was deputed by the Ceylon Government to report on Indian Railways in 1895, is sufficient to illustrate the position, Sabarmati being a goods transshipment yard near Ahmedabad on the Bombay-Baroda line :—

“It has often been said that, with proper management, a block or serious delay of traffic at a transfer station should never occur. To this I have only to reply that at Sabarmati, the junction between the Rajputana-Malwa (metre

gauge) and the Bombay-Baroda and Central India (standard gauge) Railways which, it is to be noticed, are both under the same management, such blocks of traffic are, I understand, by no means unknown. The first result of such a block is that the sidings at the transfer station are choked with laden vehicles, the contents of which cannot be transhipped at sufficient speed; all available sidings at the neighbouring stations then become similarly choked with vehicles, the goods stations throughout the line become choked with traffic, which cannot be despatched owing to the insufficient supply of wagons, and then the mischief extends in both directions, causing complete dislocation of all traffic arrangements, until by the most strenuous efforts the block of wagons at the transfer stations are removed. If this state of affairs can occur when the two railways are under the same management, it is evident that it is still more likely to happen when the lines are under different ownership."

Although the above report was written in 1895, it is equally applicable to railways in general at the present day. In fact, so far from showing an improvement, the present position has become worse with the general growth of traffic. The general public who become aware of a difficulty in supplying wagons, but who do not know the cause, assume that the railways are not sufficiently equipped with rolling stock, and set up a clamour for more wagons. Whereas it is evident from the above description that what is required is not necessarily more wagons but a greater synchronisation of movement between the two gauges, hardly attainable under the most careful management, and therefore irremediable under the dual gauge system.

It may be said that blocks occur even on railways of the same gauge. That is true, and the remedy for that is greater terminal and junction facilities. But while reforms are needed in this direction also, the railway system as a whole can never be made an efficient transportation machine so long as the greatest evil of all, namely, break of gauge, is tolerated.

Even if we look at the least important factor in transshipment, namely, the actual handling charges, equivalent to say 10 or 20 miles of extra haulage, at every transshipment station for every ton transhipped the

question arises, why should trade be handicapped by such an extra charge *in perpetuo*, if a uniform gauge is a practicable proposition to any degree?

The above considerations are, I hope, sufficient to furnish a reply to the first point at issue, namely, that the perpetuation of the dual gauge is *not* to the public interest.

THE GAUGE DILEMMA.

Before proceeding to the second point at issue, the difficulties of the situation must be considered. Unfortunately the gauge problem appears to have been studied hitherto almost entirely from a purely railway point of view. To a railway administration a break of gauge is a nuisance to the extent that, besides holding up wagons unnecessarily, it involves the perpetual task of arranging for the transfer of consignments from one gauge to another. But from a dividend point of view railways do not appear to suffer much by these inconveniences. So long as they can carry in their own time all traffic offering itself in the course of the year, without guarantees as to date of despatch or time of transit, their obligations to the public are, I believe, legally fulfilled and their earnings are more or less assured. It is probably for that reason, and in the absence of an enlightened public opinion, that railways have hitherto made no real attempt to initiate a unification scheme.

I do not make this suggestion in disparagement of railway administration, I merely put it as a possible psychological explanation of the existing state of affairs.

Possibly the reason that the recommendations of 1889 were never acted up to was because they did not carry sufficient conviction in the face of vested interests at that time, and possibly because there was no public opinion on the subject. Moreover, the subject was not so well understood then as it is now. In the circumstances it is not unnatural that the metre gauge, being the minor gauge, would strain every nerve to secure what it believed to be vital to its own interests, and the present day map shows that its achievements have been considerable and its potentialities very great. Its most noteworthy achievement, in the tactical sense, was perhaps the Cawnpore-Barhwal link, already referred to. The material success of this link from the metre gauge point of view

has rather tended to obscure its objections on more general grounds. It may be supposed that its inception was due to the theory that trade would be fostered between the metre gauge regions of the Bengal and North-Western and the Rajputana-Malwa by connecting them with a metre gauge link. This theory, confirmed by results, clearly demonstrates what a deterrent effect the previous break of gauge must have had on the flow of traffic interchanged between the two areas. Nowadays, however, defenders of the dual gauge are prone to argue that the evils of the break of gauge are insignificant. But we cannot have it both ways. If the latter hypothesis is true, then the Cawnpore-Barhwal link was an unnecessary expense. On the other hand, if the evils of break of gauge are admitted, then the true remedy would appear to be, not connecting links to maintain the minor gauge, but conversion of the minor to the standard gauge as traffic develops, in order to remove the need for transshipment. These are the sort of reflections that the existence of the Cawnpore-Barhwal link will always give rise to, unless the link is regarded merely as a temporary stop-gap, fulfilling a useful purpose at a certain stage of the evolution of railway traffic, pending final conversion.

Another example of the influence of gauge on the trend of traffic occurs in the case of the Fazilka-Kotkapura-Bhatinda branch of the Rajputana-Malwa metre gauge railway, which is worked by the Bombay-Baroda administration. This branch, about 77 miles long, of which Fazilka-Kotkapura is about 50 miles, was in existence before the broad gauge railways which immediately surround it were constructed. Consequently the traditional port for Fazilka traffic is Bombay, although the nearest port by rail has, for many years, been Karachi. The latest broad gauge line is that connecting with Fazilka on the west side, and it is significant that since the construction of this line the proportionate flow of traffic from the Fazilka-Kotkapura section for Karachi, as compared with that for Bombay, has been slowly but perceptibly increasing, in spite of the break of gauge at Fazilka. The inference is that traffic from this region would always have been for Karachi, in preference to Bombay, if it had not been for the metre gauge offering the least line of resistance for so many years. It would therefore be obviously to the public interest to convert

this section to the broad gauge, thereby, incidentally, saving the redundant Kotkapura-Bhatinda link, 27 miles long, which would go a long way towards paying for the conversion, even though the interests of the Bombay-Baroda administration might be slightly affected.

SUGGESTED REMEDIAL MEASURES.

I now proceed to formulate my proposed measures to alleviate the evils of the dual gauge. They are based on the natural growth of traffic on every railway. When the traffic begins to exceed the capacity of a single line, the railway is faced with the alternative of doubling or conversion to a wider gauge. In the case of the metre gauge the cost of conversion to broad gauge is, generally speaking, rather less than that of doubling, while the immediate effect of conversion is to double the capacity of the track. The point to note is that all railways must incur additional capital expenditure from time to time to meet the natural growth of traffic, so that, if it became a recognised rule that the metre gauge railways, which, as already noted, are still practically all single track, should be converted to broad gauge in preference to doubling as soon as their traffic exceeded the capacity of a single track, the metre gauge would be automatically eliminated in course of time, practically without incurring any expenditure beyond that which would have to be incurred in any case to meet the growth of traffic. So much for existing metre gauge lines. An exception might be made in the case of Burma and the Assam-Bengal railway, which being more or less isolated from the general railway system of India, could be left out of the conversion scheme for an indefinite period without detriment to public interests. Other metre gauge areas would also be left undisturbed so long as the traffic was insufficient to justify conversion.

The construction of new lines on the metre gauge would have to be restricted by legislation in such a way as not to further prejudice the position.

To meet the objections of those who argue that the poorer and undeveloped districts of India would not yield sufficient traffic to make a new broad gauge line pay its way, I propose that 2' 6" and 2' feeder lines be permitted as at present, on the understanding that such lines be converted to broad gauge as soon as the growth

of traffic is sufficient to justify the cost of conversion.

The above are the three salient features of a policy which, if carried out intelligently and consistently, would rid India, in course of time, of the curse of the dual gauge without involving more expenditure, practically, than that required to meet the natural growth of traffic.

In considering the practicability of carrying out such a policy, it should be noted that the principal railways of India are state-owned, of which three are also state-managed, the remainder being company worked on such terms that Government gets by far the greater share of the profits as the predominant partner. Moreover, the present time is specially favourable for considering the question, for the recent five years' programme, drawn up by the Railway Board, shows that all available money for the next five years will be required for the rehabilitation of existing lines, so that the construction of new lines will be practically suspended during that period.

Of course, it is to be expected that each feature of the proposed scheme would have its opponents. For instance, it has been urged that the conversion of the main line of the Bengal and North Western would involve the creation of about thirteen transshipment points at the junctions of its main line with branches, unless the latter were converted too. Against this may be set the fact that at least a dozen existing transshipment points with other railways would be wiped out automatically by such conversion, not to mention the credit obtained from the dismantling of the existing 80 mile Cawnpore-Barhwal link, which would by this scheme automatically cease to serve any purpose. As between the dozen or so local transshipment points which would be created by conversion and the existing dozen inter-railway junction transshipment points which are now necessary, there is no doubt that the public would prefer the former alternative if for no other reason than that such points would be nearer the consignor or consignee, as the case might be. Moreover, on general grounds, the aggregate tonnage which would be transhipped between branches and main lines would presumably be less than the aggregate tonnage of main line and branches combined to be transhipped to other railways and vice versa, so that such a move would be

a distinct step towards mitigating the evils of break of gauge. As regards dividends, there is no reason whatever to suppose that dividends would be adversely affected by conversion, any more than they would by doubling. It is to be borne in mind that my proposals do not involve the conversion of a single metre gauge line before the traffic reaches the limit when the choice between doubling and conversion is forced on the railway. On the other hand, I do not believe that there is a single metre gauge railway that would not benefit by conversion when the time came. It is an established fact, though not sufficiently recognised, that the working of the metre gauge is inherently less economical than that of the broad gauge; that is to say, for a given volume of traffic in a given tract of country, and under a given administration, the cost per ton-mile or per passenger-mile, would be less on a broad gauge railway than on an equivalent metre gauge line. As regards capital cost, we have already seen that the cost of a railway depends more on the volume of traffic than on the gauge. The only conditions under which the gauge is an appreciable factor of first cost is (1) when the traffic is very light, and (2) when the country is very easy, especially when the track is allowed to be laid on an existing public road. This is shown clearly in the diagram (Fig. 2). In such circumstances, a 2' 6" line would be obviously cheaper than a metre gauge at first cost, while it would be capable of meeting a growth of traffic by the provision of additional rolling stock and other facilities, from time to time, until the volume of traffic attained sufficient proportions to justify conversion to broad gauge. Thus the whole of the traffic of India could, in course of time, be worked by the broad gauge, supplemented by narrow gauge (2' 6" or 2' 0") feeder lines, so that the use of an intermediate gauge, such as the metre, would be superfluous.

Against the contention that capital cost depends more on volume of traffic than on the gauge, it is sometimes pointed out that the sharp curves which are possible with the narrow gauge as compared with the broad make a great difference in the cost of earthwork, as between the gauges in mountainous country. My reply is that such reasoning would apply only to certain mountain railways, which, being always of a special character, hardly come within the

Fig. 2.

scope of the gauge problem. The majority of narrow gauge lines are laid in very easy country, so that the sharpness of the curves used has no material effect on the cost, as compared with other factors.

As regards the proposed restrictions on the construction of new metre gauge lines by legislation, I believe legislation to be necessary as the only way to secure continuity of policy in the direction of unification, which is what is badly wanted.

To this end I proposed, in my paper to the Institution of Civil Engineers, that the Indian Railway Act be amended and enlarged so as to include a section dealing with the gauge question, the provisions of the section to be somewhat as follows :—

- (1) This section of the Act shall apply to all parts of India, except Burma and Assam.
- (2) The 5ft. 6in. gauge shall be the standard gauge.

- (3) Any railways or portions of railways under the operation of this section of the Act not conforming with such standard gauge shall be converted to that gauge when, in the opinion of the Governor-General in Council, such conversion is required in the public interests.
- (4) The construction of all new railways shall be on the standard gauge, except as may hereinafter be provided.
- (5) Subject to the operation of Clause 3 :—
 - (A) Lines of light traffic, when cheapness of first cost is an important consideration, may be constructed on the 2' 6" gauge, or on the 2' gauge in case of extension of existing 2' lines.
 - (B) A new line may be constructed on the metre gauge only on the following conditions :—
 - (i) that it is an extension of an existing metre gauge line ;
 - (ii) that it does not connect with or cross over a standard gauge line.

N.B.—Under this sub-head, connection means the provision of direct tranship arrangements.

Before leaving the subject of legislation, I may recall the fact that the present uniformity of gauge in the United Kingdom is due to the timely legislation of the forties, and that the confusion of gauges which exists in Australia, South America and other countries, is due to the absence of such legislation in those countries.

It may be said that the above measures would not be sufficiently elastic, but I am of opinion that, taken as a whole, such a policy would be infinitely more satisfactory than the present opportunist formula of treating every case on its supposed merits, without reference to any recognised guiding policy, by which gauge questions are settled under present circumstances.

I will conclude by saying that I fully appreciate the merits of the metre gauge, but the point is that it is too good for a mere supplementary gauge. Its virtues are the strongest arguments against its retention. For as long as it exists it will strive to extend its activities in competitive areas, and thus aggravate the evils of the dual gauge to the hindrance of real progress in transport efficiency and commercial interests as a whole. If unchecked it will

lead to an expensive struggle in which the broad gauge must ultimately prevail, because, as I pointed out in my paper to the Institution of Civil Engineers—

- (a) The capital sunk in it is already more than double that of the metre gauge.
- (b) It now carries 80% of the total railway tonnage of India at remunerative rates.
- (c) It is inherently more economical in working than the metre gauge.
- (d) It has higher potential speeds than the metre gauge.
- (e) It is susceptible of indefinite expansion.

My proposed legislation, therefore, aims at attaining by peaceful and economical methods the ultimate removal of an incubus in railway transport in India, in the shape of the dual gauge, which it seems hardly fair, either on moral or economic grounds, to inflict on posterity.

[The Society is indebted to the Council of the Institution of Civil Engineers for the loan of Fig. 1 and for permission to reproduce Fig. 2 with certain alterations suggested in the discussion.]

DISCUSSION.

THE CHAIRMAN (Sir R. W. Gillan) said that personally he did not feel very competent to contribute to the discussion, especially in the presence of various eminent railway authorities, but he might make a few remarks, strictly as a layman. The first thing he would like to do was to draw a necessary distinction. India was a museum of railways. It contained everything, from the lordly 5ft. 6in. to the toy 2ft. That day he had heard that some authority in Bombay proposed to make a 4ft. 8½in., just in order, he supposed, to complete the collection. But these railways had in common nothing except their mere rails. A discrimination must be made between classes, and he thought the two main classes were these: (1) lines of long distance traffic or trunk communications, and (2) what might be called local lines, whether described as "feeders" or, as someone had called them, "railed roads." These two classes had to be kept very distinct, or mistakes would be made. For the local lines it might be advisable to aim at connected systems, or possibly at a network of light rails all over the country, but in any case continuity of gauge was not in their case a paramount consideration. In the case of main lines, or railways proper, many people thought that gauge was paramount, and it was perhaps at this point that the difficulties had originated over the gauge question. The

origin of the difficulties might, that is to say, lie in the fact that the metre gauge was a possible gauge for both sorts of railways. He would not describe it as falling between two chairs; rather it seemed to sit on both chairs, or perhaps one might say that it was difficult at times to be sure on which chair it was sitting, for it served both for main line communications and for feeder lines. To vary the metaphor, they might say that it made the best of both worlds, and he thought the issue before them was very much in this sense, that adherents of the metre gauge said that it was a universal gauge available for either class of railway, while the adherents of the broad gauge said that it was not the best for either. The two main questions as they appeared to the speaker were these. In the first place, was continuity of gauge a paramount consideration in the case of railways proper? Was it something to which they ought to subordinate other advantages, it might be to a considerable extent? Many of the arguments that had been brought forward in India seemed to indicate that it had this character, but in practice it had been treated as of comparatively little importance. Then, in the second place, the question was which was the preferable gauge for the main system of railways, assuming that there should be one? The arguments which had been advanced here, seemed to favour a broad gauge, but on behalf of the metre gauge it was answered that the metre gauge, at any rate, sufficed for the requirements of main line communications, and the question, therefore, transferred itself to this, whether the advantage of the broad gauge was of sufficient extent to counterbalance other considerations. He thought the views formed on these two questions would largely influence the decision taken on any particular project put forward, whether the construction of new lines or the provision of larger capacity on existing lines, but they would be complicated by other factors—in particular, traffic considerations which were of vital consequence to the metre gauge lines would often be found to have a far-reaching effect. Mr. Royal-Dawson had said that in the long run the broad gauge was bound to predominate. He thought there were two facts which went against that conclusion. The first was that the metre gauge systems, unlike Government, had a perfectly definite policy, and the second was that, also unlike Government, they were always prepared to finance what they considered desirable. The outlook generally, therefore, for this gauge question seemed to be as uncertain and as unsatisfactory as its past history had been. He thought that something ought to be done. Mr. Royal-Dawson had proposed legislation, and the speaker quite understood the considerations that had led him to that recommendation. But he was not sure that in the case of the Government of India legislation would be appropriate, seeing that they would be laying down rules, not so

much for private companies as for themselves, and in any case he would say that it was clear that in spite of all the time and discussion given to this subject, it was not yet ripe for legislation. He would turn, therefore, to the report of Sir William Acworth's Committee on this subject, which said:—"Thorough investigation of the gauge problem is urgent at this moment. We think that the situation as it at present exists, must be faced as a problem affecting the whole of India, and examined from the engineering, operating, and financial side by a special commission of two or three of the first experts who can be found after careful search not in one country only." A commission of this kind would be able to lay down an authoritative policy which the Government would be able to carry out. If he (the speaker) were on the Railway Board still, he would welcome the assistance given by a body such as was proposed by Sir William Acworth's Committee in almost every project that came before the Board.

LORD MONTAGU OF BEAULIEU, K.C.I.E., C.S.I., said he had recently returned from India, where he had been studying railway systems and railway questions in general, including this very gauge question, and he must confess that, after considering the subject generally, his conclusions were more in accord with Sir Robert Gillan than with the reader of the paper. He was inclined to take this view, not only on account of what he considered its inherent soundness, but from the point of view of finance, which in these days was the most important consideration in railway construction in India. India proposed to borrow a large sum, to be spread over the next five years, for the rehabilitation of the railways, which at the present moment could not be described as being in anything like a fit state, either to carry the existing traffic or, still less, the traffic of the future. Therefore, the problem resolved itself into this: having raised the sum in question, how could the money best be spent? He did not think that an impartial judge would advocate that any considerable proportion of it should be spent on making the gauges more uniform. What Sir Robert Gillan had said was perfectly true. The traffic in bulk from ports was distributed up country in the main and at present moment by the standard gauge. The standard gauge went to every main port in India. It carried something like 80 per cent. of the traffic. The lesser gauges distributed and collected that traffic more or less in a radial fashion, and at various stations all over India on these narrow gauges, he was struck by the very small amount of traffic which did pass over these narrow gauge lines. He spent one day examining a local line which ran eighty miles west from Cawnpore, with a view to suggesting the running of rail motor cars, and he was impressed there with the very

small amount of traffic. He was told afterwards, that it was affected somewhat by strikes that were going on to the eastward, but even so, there was no doubt that that line was not employed to anything like its full capacity, and there was room for a good deal more traffic to pass over it. When one came to the construction of new lines, he would rather see a road as a feeder to a railway than the construction of more small gauges; and the modern use of motor vehicles with the less handling which they entailed at the points of origin and destination was really an argument for a diminished construction of feeder lines, and a greater construction of roads to feed the main line station. With regard to other points in the paper, he would ask the reader to consider whether the analogy of France was not worth studying. In France, the main lines of railway had a 4' 3½" gauge, which was the standard continental gauge, but there were also very successful light railways in the north of France for agricultural purposes, in the east for minerals, and in the south for passengers and goods. To take one railway which ran on the Riviera, from St. Raphael to Toulon, it would have been impossible to have got a standard gauge with all the necessary paraphernalia of stations, signals, and so forth on this line, but although it was worked in a casual way, it was worked quite cheaply and efficiently. It was really a "railed road." The French students of railway matters had always told him that they regarded these lines purely as feeders, rather than railways proper. To attempt to reconstruct the metre-gauge railways of India would entail a very large sum of money, and to attempt to do it when there were so many other urgent things to do, such as the provision of heavier locomotives and other important matters, would be a waste of money. He thoroughly agreed with the reader of the paper in some of his statements. There was no doubt whatever that the break of gauge at some of these points was a very serious matter to the public, even more than to the railway companies. It did not necessarily affect dividend-earning capacity, but the delay in some cases prohibited perishable traffic, and in these days, when the Indian coolie was not as tractable as he used to be, and his labour was very much more expensive, the handling and transhipment of goods at these interchange points was a bigger problem than in the past. As a remedy, it might be possible to use road wagons on crocodile trucks, or trucks with very low platforms, and tranship them from one truck to the other on the railway. This was done now on the London and South-Western, and also on the Continent. Then, again, there was the use of transporters at stations. In fact, he did not admit that all the means of interchange of traffic had been exhausted. Of course, there was no doubt whatever that, as the reader of the paper put it so well, given a certain tonnage from a

certain distance and a certain number of passengers, they were conveyed more economically on a 5' 6" gauge than on smaller gauges. They must all deplore the fact that the gauges were made originally of such a diverse character, and he could only hope that, chiefly on the grounds of relative urgency, none of the borrowing for the railways of India would be spent on the alteration of gauges. But he admitted to the full that at some time in the future this gauge question would have to be considered.

SIR WILLIAM M. ACWORTH, was quite sure that they would all be grateful to Mr. Royal-Dawson for his valuable paper. In one particular the best was the enemy of the good, and that was his map, in which he had tried to show too much. If his map had merely shown the metre gauge and the 5ft. 6in. gauge, it would have brought out what he had described so well in his paper—the way in which blocks of metre gauge were intersected by and cut across by lines of the other gauge, and so would have demonstrated what an unsatisfactory position had been reached. He hoped that the map might be simplified and re-drawn when the paper was published. He (the speaker) was not an engineer, and he wanted to confine his attention to the subject of the paper as headed, which was not "The Proper Gauge Policy," but "The Need for a Policy." If the map he had asked for were in existence it would be enough to hold it up in demonstration of that need. If his recollection was correct, the Indian railways began about 1851-1855. He was rather surprised that the big English engineers as early as 1855 did not see that 5ft. 6in. was not right to start with. By that time he would have thought they would have understood that 4ft. 8½in. was good enough. He wanted to put himself in the position of the man who first started the narrow gauge. He was quite sure that that man said that the people who started the 5ft. 6in. were wrong. He must have had that in his mind, and have decided that, because they were wrong, he was going to do something else. To-day he did not think anybody would deny that the people who had produced this crisscross system were wrong. The question was, however, ought we, in 1922, to have a policy? Mr. Royal-Dawson and Lord Montagu had spoken of the large sums invested. But we were only at the beginning of expenditure on Indian railways. The whole capital investment so far was only £400 millions, one-third of the capital invested in the railways of Great Britain. There were fewer miles of railway in India, for a population of 300 odd millions, than in Canada for a population of eight millions. India was only beginning to make its railways. It had got to make a vast number more. Surely it was necessary to have a policy before they went any further. His esteemed colleague,

Sir Henry Burt, had said, "For heaven's sake, don't start out to get a policy. It will be made the excuse for the Finance Department to refuse every penny of money to go on with, on the ground that the policy is not yet forthcoming." The speaker believed that it was desirable to get a policy before building any new lines, but the amount of which Lord Montagu had spoken as about to be borrowed by the Government of India was pledged for improvements of the existing system. After these improvements had been effected, they might begin to talk about extensions, and then would be the time to get a policy. He did not think people had appreciated the absolute non-necessity for the 5ft. 6in. gauge. Before he went to India he travelled a good many thousands of miles on the South African 3ft. 6in. gauge, which was not very much better than 3ft. 3in. He travelled in perfect comfort, with sleepers and diners and so on, and on that gauge in South Africa they ran trains as heavy as the heaviest train he could find in India. The heavy trains in India from the coal-fields down to Calcutta were no heavier than those run in the Transvaal on 3ft. 6in. On the other hand, take the 4ft. 8½in., it was going to be a long while before anybody proposed to take a train heavier than, say, 17,000 tons—a load that has actually been hauled by one engine in America—over these lines, so that it seemed to him that the thing was open for discussion, and it had to be discussed from the point of view, not of what was done on the 5ft. 6in. or on the 3ft. 3in., but of what might be done. With what Mr. Royal-Dawson said about transfers he was absolutely in agreement. Nearly all the witnesses before his Committee said that they were short of trucks. They were not short of trucks a bit, there were plenty of trucks to move the traffic if they could only move the trucks. You must tie up trucks and tie up roads when you come to tranship on a large scale. Why did the little original short-line railways in America and England come together in big systems? It was because they had not discovered in those days that it was possible to book traffic from one company to another on a clearing-house system. It was equally impossible to conduct a large traffic satisfactorily if there was unloading from one gauge to another. In theory they might be told that it was possible to take stuff out of one truck and put it into another in a certain number of hours or minutes at a certain number of pence or annas per ton. But that did not happen in practice, and never had done, and never would. That was the evidence all over the world. They always suffered from this break of continuity. It was worth almost anything to a railway man to get the power of working through. The best proof of it was that the Indian Government was putting up a broad-gauge line through the Khyber Pass. They knew perfectly well that they must not

have a break at Peshawar, or they would have congestion there if they did. In the event of a sudden breakdown or sudden glut of traffic the break of gauge was of vital importance. Frankly, he did not see why legislation was required. What was required was a policy, and if such a policy were established and the Government strong enough to carry it out, it would pay the Government over and over again to be very generous in the case of a light railway that lost its traffic. It was a policy which was wanted, and not legislation. To the speaker this was King Charles's head. Why was there not a policy? Because India would not allow railway men to manage railway business. Why was a narrow-gauge railway made here and a narrow gauge railway there? Because the Finance Department said that it would cost an extra two lakhs or three lakhs, and that they had to balance the Budget. As long as that attitude was accepted he saw no hope for a policy. The essence of the question was that this was a matter which railway men understood and ought to understand; it was not a matter which financial people understood, and the railway men must be trusted to do it. If the matter were put to the Railway Board and they were told to present a policy, which it was their business to find, he was sure that they would go further and say that India was *qua* railways a single entity. It did not connect with railways anywhere else in the world. On the other hand uninterrupted communication throughout India itself was vital. The men who came home from India came home usually to England, probably the country least desirable from this point of view, to have its railways studied. He was sure that the Railway Board could profit by the experience of the people of Australia, who were face to face with the same problem. He had not seen the report made on the complicated problem of the gauge in Australia. But he was certain that in the long run—and not the very long run—it would pay abundantly to have a policy, and that policy ought to be threshed out on the understanding that it was to be a permanent and continuous policy and not interrupted by financial opportunism which had been mainly responsible for the confusion. If Mr. Royal-Dawson could revise his map it would do more for the cause he had at heart even than his very interesting paper.

SIR CHARLES H. ARMSTRONG said that like the Chairman he could only deal with the matter as a layman. He was not a railway engineer nor a traffic or transportation expert. But he had some knowledge of the administrative work of a railway in India, and also of the commercial and industrial needs of India in general, and he thought this a very important factor in the question under discussion. They had been told that in 1851 the 5ft. 6in. gauge was decided upon as the standard gauge for India.

The first railway to be opened was in 1853. It was a short length of 21 miles from Bombay to Thana. In 1869, owing to financial reasons, it was decided to inaugurate the metre gauge system. In 1889 the broad gauge was again in the ascendant; a few years later it was decided to link up the different sections of the metre gauge, and he could not help thinking that if a decision was to be come to such as Mr. Royal-Dawson suggested, and a definite policy was laid down by an amendment of the Act—though he agreed that an amendment of the Act was not necessary, because the railway policy of India was entirely under the control of the Government of India—a few years hence, owing to financial or other reasons it might be found that a mistake had been made. At the beginning of his remarks Mr. Royal-Dawson referred to the paper read by the late Mr. Neville Priestley, and said that because Mr. Priestley was not an engineer he failed to grasp some factors which bore upon the first cost of construction of a broad-gauge line. The speaker had not read Mr. Priestley's paper, but he had no doubt that Mr. Priestley wrote it from the traffic point of view, because he was a traffic expert of great experience and a man of very far-seeing views. There could be no doubt that the great need of India at the present time, especially from the commercial point of view, was a great extension of her railway system. He remembered petitions, perhaps forty years ago, being sent to the Secretary of State by Chambers of Commerce in the North of England, particularly Manchester, urging the need of a much more rapid extension of the Indian railway system. If the need was urgent forty years ago, it was very much more urgent to-day. After seventy years there were only 37,000 miles of railway in India. Nothing was done in the way of extension during the War, and so far as he could see from the railway programme nothing was likely to be done in the next few years. The result would be that in very nearly eighty years the annual rate of progression would only have been 500 miles. This was very slow progress indeed. The financial question had dominated the position for a long time, and so far as he could see it was likely to continue to do so for many years to come, unless—he feared it was a vain hope—the people of India could be induced to put their money into the extension of their own railways, as the British public did many years ago. One had only to judge from the evidence lately given in India before the Royal Commission. The one cry was State management, control, and finance, which meant that the Government of India were to borrow the money wherever they could at a fixed rate of interest, and their power to borrow was, of course, limited. He was surprised by the recommendation in the paper that when a metre gauge line had reached its capacity it should be converted to a broad gauge rather than that it

should be doubled on the metre gauge. He could not but think that traffic could be passed along a double line very much faster than along a single, and if that was so he felt that it would be a mistake to follow the plan which Mr. Royal-Dawson had suggested. There was another remark in the paper which also rather surprised him. It was said that if the railways of India could carry in their own time, without any guarantee as to date of dispatch or length of time taken in transit all the cargo offered to them, they had fulfilled their obligations to the public and had earned their dividends for their shareholders. He did not think that the railways of India regarded the movement of traffic from this point of view. There could be no doubt whatever that the future prosperity and wealth of India depended upon a great increase of her internal and external trade, though he was bound to admit that one would not imagine this point was realised from much of the evidence given lately before the Fiscal Commission. If the merchants of India could only get raw materials brought down to the coast in half the time it took to-day the external trade of India would be very greatly increased. What, of course, was needed in India was more and more railways. There were only 18,000 miles of broad gauge, and very nearly 19,000 miles of metre gauge and narrow gauge. He did not himself see how, having gone so far, they could go back, and he thought they would have to continue as they were, each project as it came forward being considered strictly on its merits. He had no doubt that, if it was dealt with in this way, every point Mr. Royal-Dawson had urged that afternoon would be carefully considered, but it would be a mistake to say that the policy in future should be only 5ft. 6in. gauge. There were many tracts in India which required opening up, where a 5ft. 6in. gauge would never pay, whereas a metre gauge might pay. He hoped that in future the extension of Indian railways would be very much more rapid than in the past.

SIR THOMAS H. HOLLAND, K.C.S.I., F.R.S., said that Mr. Royal-Dawson, referring to the damage done to goods by delays, had stated that the Indian public, who had been brought to regard this state of affairs as inevitable, did not appear to realise what a difference uniformity of gauge would make. The public of India had been shouting so much for the last generation for more waggons that they had become too hoarse to voice their views with regard to the cause of the shortage. The public, after all, was not in a position to analyse the causes for the grievances from which they suffered. The troubles that arose from a break of gauge did not affect to the same extent the portion of the public that was able effectually to make its voice heard through the Chambers of Commerce. With the single exception of the Upper India Chamber at Cawnpore, most

of the important Chambers were interested in the external trade of India, which was brought to and distributed from the ports. They were not, therefore, as merchants, interested in the change of gauge. The shipping firms at the ports very rarely saw any of these inconveniences which affect the up country small merchant and the inland industrialist. The whole railway atmosphere of India had acquired a psychological bias in favour of external trade. Vested interests had grown up and become firmly rooted with the help of this fertiliser. He would not say that the policy was wrong. Its effect had been distinctly to the general good of India, and those who would have to handle the new and very dangerous weapon of fiscal independence, would be wise to go very delicately indeed in the matter of external trade. The uncertainties of delivery were among the most serious of the grievances of the inland industrialist to-day. It must not be imagined for a moment that these were all due to the break of gauge. One knew quite well that delays occurred also on main lines. But they were paralysing the trade. They were paralysing the trader who had to think financially ahead, with the necessity of keeping an exact timetable, and meeting his payments from his receipts. But the practical problem, it seemed to him, had been rather overlooked in that discussion. The problem of immediate importance was not to settle whether the broad gauge or the metre gauge was the better, not even to decide whether the dual gauge was good or bad; the problem was to find out when and how the change could be effected. There was more than this. The problem was to convince those who had the power of sanction and those who had the power to act, and these in his experience were not likely to be moved by any kind of arguments or facts that were not reinforced by an authoritative and impartial committee. After all, there were vested interests to be disturbed, and those who were hurt most would certainly make most noise. Sir William Acworth's Committee recommended that whilst the gauge question was really urgent it should be separately examined from the engineering, operative, and financial points of view by a special Commission. The Acworth Committee would not even suggest a solution themselves. There were points in the paper read by Mr. Royal-Dawson which would be likely to send the criticism in the wrong direction, among them the point referred to by Sir Charles Armstrong. "All railways" (said Mr. Royal-Dawson) "must incur additional capital expenditure from time to time to meet the natural growth of traffic, so that, if it became a recognised rule that the metre gauge railways, which, as already noted, are still practically all single track, should be converted to broad gauge in preference to doubling as soon as their traffic exceeded the capacity of a single track, the metre gauge would be automatically eliminated in course of time,

practically without incurring any expenditure beyond that which would have to be incurred in any case to meet the growth of traffic." He (Sir Thomas Holland) took it for granted that any increase in traffic sufficient to call for the doubling of the track would occur on certain sections first and not on the whole line. Doubling one section would be possible and obviously advantageous, but conversion of one section to another gauge would merely add to the embarrassment. The conversion to broad gauge in preference to doubling as soon as the traffic exceeded the capacity of a single track, was not likely to appeal to the administration of any of the lines concerned. Reform would not arise spontaneously. Reform would not be effected except by force, and force would not be justified until it was shown by a judicial and impartial commission that conversion was really necessary in the public interest. It was no use arguing in that room that it was desirable. They had to show how reform could be made. Railway administrators were not obstinately opposed to conversion. They knew that there were other ways of employing their capital, and that the difficulties in the way were expensive. Take the Committee's report of 1889. They laid down a rule that when links were to be constructed connecting metre gauge with broad gauge systems they should be either constructed on the broad gauge or should be so constructed as to be easily converted to the broad gauge. He quoted instances to show that that rule had not been observed faithfully. The present metre gauge administrations were likely to give more satisfaction out of working things as they found them than by criticising their predecessors and talking about policy. They must carry on as they found things. A simple unmodified law might not be practicable under present conditions, but still much might be done by way of conversion. There was the question of settling some order of precedence in the operations necessary even if conversion were accepted as advantageous generally. There might for example be certain areas on the peninsular section of India which were sufficiently self-contained to be left alone for the time being, like Assam and Burma. He was not inclined to follow Mr. Royal-Dawson in what he had said about stirring up public opinion. He did not see how public clamour would help either the Railway Board or railway administrations. The members of the public were in no position to examine this question critically. It was not a simple question of metre gauge versus standard gauge, but a matter of discrimination locally as to where conversion was practicable and where it was desirable after the conflicting interests had been carefully balanced. They had to determine a programme by which the Government could act. It could not be done wholesale, it would not be done in a day, and any attempt to propose that would merely result

in nothing being done at all. The best line to follow now, therefore, was to support the Acworth recommendation for a special expert examination of the whole question.

MR. FRANCIS J. WARING, C.M.G., M.INST.C.E., thought there was no doubt whatever that the need for a railway policy in India was essential, but he could not agree with Mr. Royal-Dawson in his advocacy of the construction of 2' and 2' 6" gauge lines to be converted when required into 5' 6" gauge lines. What he proposed was put forward as an alleviation of the present state of affairs, but to the speaker it appeared to be merely an aggravation of the evil which he so strongly deprecated, for Mr. Royal-Dawson was as fully aware of the folly of a break of gauge and the loss it entailed as anyone. Therefore it was surprising to him that he should advocate the multiplication of breaks of gauges all over the country. (Mr. Waring was not now speaking as an advocate generally of one gauge more than another; he was merely mentioning what he could not help believing would be an aggravation of the present evil.) Mr. Royal-Dawson talked of the conversion of the 2' 6" gauge into 5' 6"; such a conversion would cost a great deal more than the conversion of the metre gauge line into the 5' 6" line, and as the Government of India had prescribed limiting curves of different gradient for lines of different gauges, the conversion of this very narrow gauge would often be almost tantamount to building a new railway altogether. It was a fallacy for railway engineers nowadays to talk of sharp curves being incompatible with a 5' 6" gauge. The introduction of the metre gauge into India was a mistake, and the really economical measure in 1869 or 1870 would have been the construction of light standard gauge railways. He was not defending the standard gauge of 5' 6" *per se*, but what he had always objected to was the break of gauge, and having that gauge which was still predominating he considered it should be adhered to. Railways having a gauge of 5' 6" had been built in Ceylon for £3,617 per mile, in New South Wales for £3,303 per mile, and in Victoria for from £2,000 to £3,000. There were certain branches of the Indian Midland which cost between 58,000 and 67,000 rupees per mile. In these heavy rails were laid. If lighter rails had been used a very appreciable economy would have been effected, because as a rule, in most ordinary railways in India and Ceylon, the cost of the permanent way was the greatest separate item in the cost of construction.

SIR THOMAS BENNETT, C.I.E., M.P., said that he must resist the temptation to embark upon the subject of Mr. Royal-Dawson's paper, though he would have greatly liked to have taken up some of the points. But he

wanted to say something about the paper and the reader of it. The paper was admirable. It more than came up to the standard—a very high one—of the papers read before the Royal Society of Arts in the Indian Section. Mr. Royal-Dawson had done a service to India, for any contribution to the discussion of railway matters in India at this moment and in England would do good. They wanted to interest the public in England, and above all in the city, in every aspect of the railway question in India. Mr. Royal-Dawson, therefore, had done great service in laying such an admirable paper before them, and he was sure they would accord a vote of thanks to him for the labour and skill with which he had dealt with the question.

SIR LIONEL JACOB, K.C.S.I., seconded the vote of thanks, which was carried unanimously.

MR. ROYAL-DAWSON acknowledged the vote of thanks, and said that on account of the lateness of the hour it would not be possible for him to reply in detail to the discussion. It had been a great satisfaction to have elicited so many comments and criticisms, and there were a number of points on which he would like to make a reply, but he would send his reply in writing for publication in the *Journal*.

MR. SIDNEY PRESTON, C.I.E., C.B.E., writes:—If there had been an opportunity for me to speak at Mr. Royal-Dawson's paper, I had intended to emphasise more fully than Mr. Waring did in the limited time at his disposal the absurdity of trying to do away with the metre gauges while a third gauge—2' 6"—is being deliberately introduced. I ventured to comment upon this point in the discussion on the late Sir F. Upcott's paper at the Institution of Civil Engineers in 1906. At that time I think the length of these little gauges amounted to about 1,100 miles; these now total 3,500 miles, and are therefore showing considerable expansion when it is remembered that there has probably been little or no new construction in the last eight years.

In my remarks referred to above I particularly drew attention to the line then under construction, or just completed, from Saharanpur to Ghaziabad. This line traverses probably one of the richest agricultural tracts in the country, being all watered by the Eastern Jumna Canal. It connects two standard gauge lines, so that anything arriving at either end for forward dispatch must be transhipped. How Mr. Royal-Dawson, after detailing the evil and delay of transhipment, can contemplate an extension of their narrow gauge I am unable to understand. It seems to me that the introduction of the 2' 6" gauge is simply making confusion worse confounded.

I believe that the official justification for their third gauge is that the 2' 6" lines are "tramways" made under the Indian Tramways Act and

are not "railways" under the Indian Railway Act. This may be the reason, but it seems to me it is a distinction without a difference; to all interests and purposes these 2' 6" tramways are railways, and as sanction to them can be given by the Local Governments, instead of requiring the sanction of the Government of India, as in the case of railways, there is likely to be a considerable increase in the mileage when money for construction is available.

I venture to think that the question of the 2' 6" gauge deserved more consideration than was given to it by the author. The Chairman referred to the "museum" of gauges in India from 2' 0" to 5' 6". He might have said from 1' 6" to 5' 6", as there is a considerable length of 18" gauge in Gwalior State.

MR. S. M. RYAN, F.L.S., late India Forest Department, writes:—The solution of the problem of the battle of the gauges in India and Burma seems to lie in the direction of adopting Mr. Royal-Dawson's suggestion of the gradual conversion of all existing narrow gauge systems into a standard gauge and the introduction of road motor transport as feeders to all the railway lines.

The practical application of this policy would of course be contingent on adequate and cheap power being available for the efficient carrying out of road transport operations. Apart, however, from petrol, it has all along been believed that power from indigenous material was not at hand in either India or Burma for such a purpose, but this it is felt is a mistaken idea.

A proposal is in the course of submission to the Government of Bombay, at any rate, to show where and from what substances it can be produced in that Presidency, and that it only needs organisation and the expenditure of comparatively little capital outlay to enable such power to be made available.

If successful for the G.I.P. and B.B. and C.I. and Southern Mahratta lines, the scheme could be introduced in the Central Provinces, Bengal and elsewhere.

Just as water forms the basis of raw material for the execution of hydro-electrical schemes so large reservoirs of energy lie dormant in the forests of India which can be tapped with the aid of a little foresight and comparatively small capital outlay, and without disturbing the existing demands on them.

As three crores are to be spent on the improvement of the existing railways in India during the next five years (there is to be no extension of such lines, in this period, be it remembered), a few lakhs out of this might reasonably be earmarked for the development and extension of road motor transport operations if such can be demonstrated to be a practical proposition.

MR. ROYAL-DAWSON writes:—

I have to thank all the speakers for their interesting contributions to the discussion.

Sir Robert Gillan's division of railways into two distinct classes, namely, main lines and feeder lines, bears out the trend of my arguments. As he shows, the gauge question owes its complications to the fact that the metre gauge has been made to serve both functions concurrently with the existence of broad and narrow gauge lines which fall naturally into those two divisions. As the metre gauge has become a main gauge, the point at issue is whether there is room in India, any more than in any other country, for two main gauges. I fully agree with Sir Robert that the question cannot be settled authoritatively except by a specially appointed Committee of experts, as recommended by Sir William Acworth's Commission, and I should be glad to see the formation of such a Committee.

Lord Montagu of Beaulieu suggests that, as all available money for railways will be needed for the rehabilitation of existing lines for some years, there will be nothing available for conversion. But this is not quite my point, which is that the question of conversion need not arise until a metre gauge line is compelled by traffic considerations to choose between doubling and conversion. There are several sections of metre gauge railway now confronted with that alternative. Hence the urgency of establishing a definite policy at the present juncture. On the other hand, Lord Montagu's reference to the lightness of existing traffic on some of the lesser gauges, with special reference to a local metre gauge line near Cawnpore, confirms my contention that the metre gauge is unnecessarily capacious for lines of really light feeder traffic. His advocacy of the use of feeder roads for road transport in preference to light railways is well worth consideration, in view of modern developments in road transport. Speaking of the two gauges in France, it is interesting to note that the narrow gauge railways in that country are confined to light and local functions, so that no gauge complications can arise in long distance traffic on main lines, which are all of uniform 4' 8½" gauge. It is satisfactory to note that Lord Montagu appreciates the evils of break of gauge in connection with the transportation of goods. No doubt actual transshipping arrangements could be improved to a certain limited extent.

Sir William Acworth emphasises the need for a gauge policy, and suggests that this would be fully demonstrated if the map were made to show more clearly the intersection of gauges. I hope this suggestion has been carried out in preparing the book for publication. Sir William suggests that it would be time enough to consider a policy when a programme of extensions is contemplated, as all available money is now pledged to the rehabilitation of existing systems. But, as I have already pointed out, several existing sections of metre gauge line are now faced with the alternative of doubling or conversion. It is a question, not of rehabilitation

nor of extension, but of increasing capacity to meet the growth of traffic. Pending the investigations of an expert committee, such as he recommends, such sections of line might be able to carry on a little longer with the aid of "train control" and other devices for increasing the capacity of a single track, but the ultimate policy to be adopted must be decided on, for better or for worse, in the near future. Sir William's reference to the 3' 6" gauge in South Africa would appear to imply that the metre gauge might meet all requirements in India. I have no personal experience of South Africa, nor of the average distances of transit there, but I believe that the country enjoys a more temperate climate than that of India, so that it does not follow that what suits one country would suit the other. Although Sir William cites the broad gauge coal trains between Calcutta and the coalfields as being no heavier than the goods trains in the Transvaal, I might suggest that the tonnage capacity of a train is not the sole measure of efficiency. The potential speed of transit is an important factor, and although in the case of the local coal trains referred to the lead is so short that the actual running speed is of small consequence, yet for long leads of several thousand miles, such as have frequently to be traversed in India, not only by coal trains, but also by trains loaded with grain and other commodities, the higher potential speed of the broad over any narrower gauge is an asset of vital importance. I am glad to note that Sir William endorses my views as to the evils of break of gauge.

As regards legislation, Sir Charles Armstrong shares Sir William's view that what is required is a policy, not legislation. But I am doubtful whether a consistent policy can be secured without legislation. Sir Charles questions my advocacy of conversion in preference to doubling in the case of a metre gauge line when the traffic has reached the capacity of a single track. My reply is that a broad gauge single track has roughly double the capacity of a metre gauge single track, and that conversion can usually be effected at slightly less cost than doubling. It is true that a double track has at least three times the capacity of a single track on the same gauge. But the point is that a metre gauge line does not require its capacity to be trebled at one step, the increased capacity resulting from conversion would suffice for at least 20 years' further growth of traffic, while the mere fact of conversion would at once confer on the railway concerned the freedom of India, so to speak, in the railway world, which would be an inestimable advantage, without incurring more expenditure than it would have to face in any case to meet its traffic requirements. It may of course be admitted that the conversion by sections of a metre gauge railway might cause some inconvenience during the transition period, but all remodelling schemes and improvements cause temporary inconvenience, the

minimising of which depends entirely on the powers of organisation and administrative abilities of the executive staff. Of course, a carefully thought-out programme would have to be worked to in every case. Sir Charles' remark as to the need for quicker transit of raw materials from the interior to the coast in the interests of external trade, is an argument for an unbroken broad gauge for long distance traffic from all centres of production to the ports, for only on such conditions can the best results be obtained. He also advocates, as I do, light feeder railways for areas of very light traffic where a broad gauge would not pay, but in such cases I recommend the 2' 6" gauge as cheaper than the metre, restricting the use of the latter only to purely metre-gauge areas so long as such exist.

Sir Thomas Holland's remarks on the gauge question from the point of view of Chambers of Commerce are most valuable. He emphasises the importance of fostering external trade, and points out that delays in transit from the interior to the ports have the effect of paralysing trade. The remedy, therefore, is to improve the speed of transit. As regards the means of effecting this, he favours the appointment of a committee of investigation as recommended by Sir William Acworth's Commission. He shares Sir Charles Armstrong's doubts as to the efficacy of converting metre gauge lines in preference to doubling, but I have already dealt with this point in my reply to the latter. I foresee that the question of conversion versus doubling will be very controversial in individual cases, and that there will usually be a strong local temptation to double, as following the line of least resistance, regardless of whether such a course would be best in the general interests or not. It is for this reason that a clear-cut policy should be decided on in the near future, before metre gauge railways have had time to prejudice the position further by embarking on a programme of doubling. My point is that the question, being of imperial importance, should not be left to the choice of the railway concerned, and that all proposed doubling schemes should be held up at least until the special expert committee referred to has made its investigations and submitted its report. Sir Thomas Holland deprecates the suggestion that public opinion should be stirred up. But what I referred to was not public clamour, but the enlightened opinion of public men, such as those who have taken part in this discussion, and public bodies such as the various Chambers of Commerce, etc.

Mr. F. J. Waring appears to be a more ardent supporter of uniformity than I am myself, for he would have nothing but the 5' 6" gauge, even for lines of light traffic. This is no doubt a counsel of perfection, but the diagram, fig. 2, I think, fully explains by the logic of capital and interest, why in cases of very light traffic in easy country the choice may sometimes

lie between a 2' 6" gauge line and no line at all. With the recent development of road transport it is possible that in certain districts where roads can be easily and profitably constructed for facilities of administration road motor vehicles may take the place of light feeder lines to a great extent. It should be noted that the essence of my scheme is that all minor lines should be converted to broad gauge as soon as the traffic is sufficient to justify such conversion.

Mr. Sidney Preston's deprecation of the adoption of the 2' 6" gauge is partly answered in my reply to Mr. Waring. I am not enamoured of narrow gauge lines, but I am not apprehensive of their powers for evil. Mr. Preston refers to the Shahdara-Saharanpur 2' 6" line as an anomaly. But I would point out that criticism directed against a particular line because it happens to be on the 2' 6" gauge is no argument against the occasional use of 2' 6" gauge lines as feeders under any circumstances as part of a general policy. Mr. Preston may not be aware that in this particular case as in many other cases the line was required to be located so as to be easily convertible to broad gauge if so required by the Government of India. As regards the increasing mileage of the 2' 6" gauge, it should be remembered that a mile of narrow gauge railway has only about one sixth the capacity of a mile of broad gauge railway, single track, and only about one-third of the potential speed. These combined limitations will prevent it from ever becoming a main gauge, and will thus automatically preclude its use in areas of heavy traffic where a break of gauge would be a serious consideration. For the evils of break of gauge at a given point may be reckoned as proportionate to the amount of tonnage transhipped at that point.

Mr. Ryan, while advocating the ultimate conversion of all minor gauge railways to the 5' 6" gauge, favours the development of road motor transport in place of feeder lines, the power to be derived from indigenous sources. It is interesting to learn that proposals in this direction are being made in the Bombay Presidency, and it is to be hoped that the result will be successful.

In conclusion I take the opportunity again to thank Sir Thomas Bennett and Sir Lionel Jacob for their kind remarks, and the meeting for their cordial reception of the paper. I also wish to add my personal thanks to Sir Robert Gillan for having so kindly and so ably acted as Chairman.

OIL BEARING NUTS IN GUATEMALA.

The royal palm tree, especially the varieties bearing corozo and cohune nuts, grows extensively in the coastal regions of Guatemala, and although as yet little industrial use has been made of these oil-bearing nuts, they might,

writes the United States Consul at Guatemala City, become the source of an important vegetable oil industry, not only because of the great quantity of the nuts in the country, but also because of the fact that the oil content of the Guatemalan kernels is understood to be 65 per cent., in comparison with 42 per cent. for African nuts. The yield of kernels per ton of nuts in Guatemala is about 18 per cent.

On the north coast of Guatemala 60,000 tons of cohune nuts are said to be available for exportation annually and with a small expenditure on road improvement this quantity could probably be increased to 100,000 tons per annum. On the Pacific or south coast the yield of corozo nuts, it is estimated, could easily be increased to 300,000 tons per annum. There is a supply of cheap labour in this southern region.

These nuts are found almost entirely on private lands. The right to gather them is obtained from the owners by a contract, usually covering a number of years. The lack of a suitable machine for cracking the nuts or extracting the oil has been the cause of the slow development of the industry. A machine recently invented which cracks 10 nuts simultaneously has an output of about 1 ton of kernels per day. There is no plant in Guatemala for the extraction of the oil from the kernels.

PHOSPHATE PRODUCTION IN EGYPT.

The most important phosphate deposits in Egypt are found in the district of Salaja, at Kosseir on the Red Sea, and at Sabai in Upper Egypt near Keneh. According to a report by the United States Consul at Alexandria, the actual exploitation of the phosphoric beds in Egypt did not begin until 1908, when the output amounted to only 700 tons. This increased rapidly, being 1,000 tons in 1909 and more than doubling in 1910, in which year the output amounted to 2,397 tons. A further gain was shown in 1911 with an output of 6,425 tons, but the effect of development was not actually apparent until 1912, when the output reached 69,958 tons. Following that year, rail connection was established with some of the mines, with the result that Egyptian phosphate entered into foreign trade, and Egypt became a factor in the world's supply. The exports of phosphates in 1913 amounted to 64,183 metric tons, valued at £64,000.

No development was reported during the years of war, but since the signing of the armistice and the supply of adequate shipping facilities, the industry has rapidly advanced until the 1920 exports (145,072 metric tons, valued at £400,000) were nearly double those of 1919 (78,425 metric tons valued at £156,000), during which year they were greater than during any preceding year.

HYDRO-ELECTRIC POWER DEVELOPMENT IN LATVIA.

The Latvian Government is in possession of various plans for the installation of hydro-electric stations on the Duna (Dvina) River, which, for the most part, were developed by engineers of the Imperial Russian Government prior to the war. These plans constitute a somewhat complete scheme for utilizing the power of the Duna and also for developing the river, through a system of locks and short lateral canals, to make it navigable well into the interior of Russia proper, and eventually, through a system of canals connecting with the Dnieper and other Russian rivers, to form an elaborate system of internal water transportation.

According to a report by the United States Trade Commissioner at Riga, the plans contemplate the eventual installation of five stations on the Duna River to a distance of approximately 65 miles upstream from Riga. Their situation, proposed installation, cost of construction (including power stations and locks) estimated on a gold rouble basis of 1914, together with estimated cost per kilowatt on like basis, are as follows, starting with the station nearest Riga:—

Stations.	Proposed Installation.	Total cost.	Cost per kilowatt.
	<i>Kilowatts.</i>	<i>Russian roubles.</i>	<i>Russian roubles.</i>
Dahlen	24,000	10,200,000	425
Keggum	36,000	12,700,000	350
Ascheraden	16,000	5,000,000	320
Kokenhusen	80,000	11,000,000	175
Stockmanns- hof	36,000	11,700,000	325

Of these five projects, the two most seriously discussed for the immediate future are the station at Dahlen, to be utilized for the city of Riga and its industries, and the station of Kokenhusen, to be utilized largely or entirely for railway electrification. Without thorough study, adds the Trade Commissioner, it is impossible to say whether the market for electric power and the other relevant considerations would justify large expenditures in such undertakings; but at least the projects are such as to merit very serious consideration.

The station at Kokenhusen is linked up with the plans to electrify the government railways.

GENERAL NOTE.

DYES FROM KAOLIANG BRAN.—According to a report by the United States Consul at Dairen (Manchuria), a method of securing dye from kaoliang bran has been discovered by mixing it with soda, sulphate, etc. The brown and black dyes produced by this process have been patented and a patent has been applied for

to cover blue-black. Kaoliang bran may be obtained in practically unlimited quantities in Manchuria, delivered at stations of the South Manchuria Railway, at approximately 1.80 yen per 100 kin. The cost of production of black dyes is about 15 yen per 100 kin, to be sold at 25 yen per 100 kin; of brown dyes, about 60 yen per 100 kin, to be sold at 70 yen per 100 kin; and of blue-black dyes, about 25 yen per 100 kin, to be sold at 35 yen per 100 kin. (The present value of the yen is about 2s. 1½d., the kin is equal to 1.32 pounds).

MEETINGS OF OTHER SOCIETIES FOR THE ENSUING WEEK.

- MONDAY, JUNE 19** University of London, at Gray's Inn Hall, Gray's Inn, W.C., 4.45 p.m. Hon. J. M. Beek, "The Nature of American Institutions and their bearing on International Relations." (Lecture III.)
- TUESDAY, JUNE 20** Statistical Society, at the Royal Society of Arts, John Street, Adelphi, W.C., 5.15 p.m.
Mining Engineers, Institution of, at the Outlers' Hall, Sheffield, 11 a.m. Annual General Meeting. 1. Mr. E. Davies, "The Air-cooling Plant at the Morro Velho Mine, Brazil." 2. Discussion on paper by Dr. W. H. Hatfield, "Stainless Steels."
Anglo-French Society, Scala House, Tottenham Street, W., 6.15 p.m. M. Maurice Thierry, "Le Théâtre de François de Cures."
Roman Studies, Society for the Promotion of, at the Society of Antiquaries, Burlington House, Piccadilly, W., 4.30 p.m. 1. Annual General Meeting. 2. Dr. G. MacDonald, "The Building of the Antonine Wall; A Fresh Study of the Inscriptions."
- WEDNESDAY, JUNE 21** Mining Engineers, Institution of, Cutlers' Hall, Sheffield, 10 a.m. Annual General Meeting (continued). 1. Messrs. H. Rhodes and M. Rhodes, "Methods of Working the Barnsley Seam of the South Yorkshire Coalfield." 2. Mr. J. I. Graham, "Rock Temperatures in the Coal-measures." 3. Mr. A. P. Veale, "The Rate of Absorption of Poisonous Amounts of Carbon Monoxide by the Blood."
University of London, at the Royal Society of Medicine, 1, Wimpole Street, W., 5 p.m. Prof. Dr. A. A. H. Van Den Bergh, "The Pathology of Hæmoglobin."
Meteorological Society, 49, Cromwell Road, S.W., 5 p.m.
British Architects, Royal Institute of, 9, Conduit Street, W., 5 p.m. Mr. W. H. Bidlake, "The Continuity of English Architecture."
Constructive Birth Control and Racial Progress, Society for, Essex Hall, Essex Street, W.C., 8 p.m. Dr. C. W. Saleeby, "Birth Control and Eugenics—My Hopes and Fears."
Microscopical Society, 20, Hanover Square, 8 p.m. 1. Mr. A. Chaston Chapman, "The Use of the Microscope in the Brewing Industry." 2. Mr. A. Brooker Klugh, "The Plunger-Pipette." 3. Mr. E. A. Spaul, "The Gametogenesis of *Nepa cinerea* (Water Scorpion)." 4. Mr. James Strachan, "The Microscope in Paper Making."
- THURSDAY, JUNE 22** Royal National Pension Fund for Nurses, at the Royal Society of Arts, John Street, Adelphi, W.C., 4 p.m.
Royal Society, Burlington House, Piccadilly, W., 4 p.m.
Antiquaries, Society of, Burlington House, Piccadilly, W., 8.30 p.m.
Botanic Society, Regent's Park, N.W., 6 p.m.
- FRIDAY, JUNE 23** Physical Society, Imperial College of Science and Technology, South Kensington, S.W., 5 p.m.

Journal of the Royal Society of Arts.

NOTICE.

ANNUAL GENERAL MEETING.

The Council hereby give notice that the One hundred-and-Sixty Eighth Annual General Meeting, for the purpose of receiving the Council's Report and the Financial Statement for 1921, and also for the election of Officers and new Fellows, will be held, in accordance with the By-laws, on Wednesday, June 28th, at 4 p.m.

(By order of the Council)

GEORGE KENNETH MENZIES,

Secretary.

PROCEEDINGS OF THE SOCIETY.

TWENTY-FIRST ORDINARY MEETING.

WEDNESDAY, MAY 3RD, 1922.

MR. ALAN A. CAMPBELL SWINTON, F.R.S.,
Chairman of the Council, in the Chair.

THE CHAIRMAN, before the reading of the paper, said that it was scarcely necessary for him to introduce Mr. Noel Heaton, who had given numerous lectures in that hall. On a previous occasion Mr. Heaton had told them many interesting things about the pigments

used in ancient times. That evening he was to essay the more difficult task of foretelling what he thought might become one of the great pigments of the future.

The paper read was :—

THE PRODUCTION OF TITANIUM
OXIDE AND ITS USE AS A PAINT
MATERIAL.

By NOEL HEATON, B.Sc.

Some 12 years ago I had the pleasure of bringing before the Society some investigations I had made into the pigments used by painters before the dawn of history, and expressing my views as to the methods employed by that remarkable school of painting, which flourished in Crete in the early Bronze Age.* In the present paper I have jumped to the opposite extreme; my rashness increasing rather than diminishing with age, I am forsaking the fairly safe ground of archaeological research to adopt the hazardous rôle of the prophet. I propose, in fact, to discuss the latest addition which research has contributed to the palette of the painter and to submit

*The Mural Paintings of Knossos—*Journal of Royal Society of Arts*, January 7th, 1910.

to your criticism the reasons which lead me to make the bold and perhaps rash assertion that this recently discovered pigment is destined to play a prominent, if not fundamental, part in the future as a material both for the painter of pictures and the painter of houses.

For many generations past the fundamental pigment for the production of paint of all types has been white lead; for many years past there has been a growing demand for the suppression of this material on account of its alleged danger to health. Whatever may be the merits of the case, they do not concern us in the present paper; my only reason for referring to the matter being that whilst white lead has remained up to the present time the most important pigment, particularly for architectural painting, because no really satisfactory alternative has been forthcoming, this demand for its suppression stimulated research in hitherto unexplored directions with the view to finding a new white pigment which could efficiently take its place. The attempt to prohibit the use of white lead has thus led indirectly to the development of titanium oxide as an industrial material.

Before I go any further, however, with the indulgence of those present to whom such matters are perfectly familiar, I propose to answer the question which is quite naturally asked by anyone who does not happen to have studied chemistry—what is titanium?

In 1791 the Rev. William Gregor⁽¹⁾, clergyman by profession and scientist by inclination, published⁽²⁾ an analysis of a black sand which he found near the village of Menaccan, in Cornwall, where his parish was situated. This substance he found to contain nearly half its weight of a metallic oxide as yet unknown to science. Almost simultaneously Klaproth announced his discovery of the compound of a new element in a red schorl from Hungary and recognised it as identical with the substance isolated by Gregor. Klaproth gave this new metal the name of Titanium.⁽³⁾ It was not until 1824 that Berzelius prepared the metal

itself and showed it to be a dark grey substance somewhat resembling iron in appearance, although far different from it in properties, particularly as regards the fact that it is practically infusible. From that day to this titanium has remained to all intents and purposes a scientific curiosity, although some of its compounds are used industrially to a certain extent; and it is popularly classed as one of the rare elements. And yet, by a curious paradox, as a matter of fact, it is one of the most abundant substances on the face of the globe!

One of my earliest recollections as a student is that of a lecture by Sir William Ramsay on the composition of the earth's crust, in which he pointed out that after oxygen, silicon, nitrogen and sulphur, the fifth most abundant element in nature is this "rare" and little known metal titanium; and he predicted that some day it would be as familiar to us as aluminium, unknown a generation or so ago and to-day a household necessity.

The metal itself is never found in nature, but as oxide it is present in small amounts in almost all rocks, whilst it forms the principal constituent of several minerals, such as *rutile*, *anatase* and *brookite*. It occurs most abundantly, however, in combination with oxide of iron as titaniferous iron ore or *ilmenite*. Varieties of this mineral are found in various parts of the British Isles and enormous deposits exist in many parts of the world. It is of interest to note in passing, that the beautiful but little used precious stone known as *sphene*, remarkable for its optical properties, is a compound of silica, titanium and lime.

Although titanium oxide is most often found in association with oxide of iron, it bears little relation to it in its properties, which in some respects resemble oxide of tin and in others are closely akin to silica.

According to Washburn, the first use of titanium compounds as pigments seems to have been made by Dr. John Overton, of Louisville, U.S.A., about 1870. He described a process for the manufacture of titanium pigment from pure rutil as follows:

"Rutil is ground or reduced to a sufficiently fine powder, and is mixed and thoroughly incorporated with coal tar, bitumen or other liquid bituminous materials or compounds. The mixture, when completed, forms a paint which may be employed for painting ships' bottoms and other surfaces exposed to the action of sea water."

(1) See Biographical notice in *Annals of Philosophy*, 1818, p. 112.

(2) *Journal de Physique*, 1791; see also *Crelle's Annalen*, 1791 1 40, p. 103.

(3) "Whenever no name can be found for a new fossil which indicates its peculiar properties, I think it best to choose such a denomination as means nothing of itself and thus can give rise to no erroneous ideas. In consequence of this I shall borrow the name for this metallic substance from mythology and in particular from the Titans, the first sons of the earth. I, therefore, call this new metallic genus Titanium."—Klaproth, *Analytical Essays*, 1801, p. 210.

Dr. Overton claimed that his product was unaffected by salt water, formed a perfect protection for ships' bottoms and further that it was not injuriously affected by the heat of the sun, or by a temperature of 450° C.

This process did not meet with any success, the reason probably being the undesirable colour of Rutile and the great difficulty experienced in pulverising such a hard material.

The fact that titanium oxide could be obtained as a white powder which possessed in a quite abnormal degree the physical property of opacity, which should render it peculiarly useful as a pigment, has long been known, but until a few years ago it had remained unexploited.

It was not until some ten years ago that the problem of harnessing this material to industry was successfully investigated, and as so often happens in such cases, the industrial production of titanium oxide on the large scale and its application to the paint industry was started almost simultaneously as a result of researches carried out independently and as far apart as America and Scandinavia.

In the United States a pigment prepared by extracting the titanium oxide from titaniferous iron ore and combining it with calcium sulphate was introduced some eight years ago by A. Rossi and L. E. Barton. My first introduction to the possibilities of titanium white as a pigment was in 1917, when I visited Washington whilst on military duty in America. Whilst there I called at the Institute of Industrial Research and was shown by Mr. H. A. Gardner some exposure tests he had been conducting with this pigment, but I must frankly confess that at the time I was rather sceptical as to its possibilities.

Meanwhile, Dr. Jebsen and Professor Farup had been for some years perfecting a process for extracting titanium oxide from the titaniferous iron ore which is found in great abundance in Norway, notably in the neighbourhood of Stavanger, where it has been estimated that 30 million tons are available.

In 1870 this deposit was exploited by an English Company and imported to this country for use as an iron ore. It was found, however, that the high content of such an infusible material as titanium made the smelting of the ore an extremely difficult matter, and after some years' trial the

attempt to utilise it in this manner was abandoned as impracticable.

About 1908, the perfecting of the electric smelting process suggested the possibility of developing an iron industry in Norway, where electrical energy is so readily obtainable. Attention was thus directed again to this titaniferous ore, but Jebsen and Farup, knowing the difficulties in the direction of utilising it as a source of iron, started investigations with a view to utilising the titanium, rather than the iron, as the principal objective.

In the course of their investigations their attention was drawn to the remarkable opacity of titanium oxide and its probable value as a pigment. Realising the great industrial possibilities in this direction, they determined to concentrate their energies on the problem of devising an economical process of preparing the oxide on a large scale, at the same time studying exhaustively its utilisation as a pigment.

Then ensued a laborious series of researches, extending over some six years, before a satisfactory process was finally elaborated; trials of its application on an industrial scale were started in 1914. As everyone knows who has studied such matters, this translation of a process from the laboratory to the factory is the most critical and arduous part of its development and four years of untiring research elapsed before the various technical and mechanical difficulties were overcome.

One cannot but admire the magnificent courage with which the inventors, encouraged by the successful results they obtained on a small scale during this period, finally decided to put their convictions to the test by planning and erecting a plant capable of producing 8,000 tons per annum, which commenced operations in 1919.

Finally, the independent workers in Norway and the United States discovered one another, and decided on a mutual exchange of their respective experiences which resulted in a further perfecting of their processes and a more complete study of the many scientific points involved.

A description of the preparation and properties of the pigment was published in a paper read before the Paint and Varnish Society last year by Mr. W. F. Washburn,* from which paper I have derived some of

* W. F. Washburn and J. McGougan. Titanium White, its Production, Properties and Uses. Proceedings of the Paint and Varnish Society, March, 1921.

the data included in the present paper.

Considerable interest was aroused by the publication of this paper, but like a good many others I was still somewhat sceptical as to the properties claimed for this new product. In February of this year, however, I had the opportunity of visiting Norway and studying the process as carried on there in detail, with the result that I have formed the opinion I expressed at the commencement of this paper.

The process of manufacture of this interesting pigment, as now established in Norway, is a most ingenious one, and I will now show you a series of slides which illustrates its main principles.

The titaniferous ore found near Egersund, south of Stavanger, consists mainly of a variety of ilmenite, to which the formula $\text{Fe}(\text{Mg}) \text{TiO}_3 + 10 \text{Fe}_2\text{O}_3$ has been assigned, together with associated minerals, principally magnetite, hypersthene, and apatite, with a small quantity of vanadium. This crude ore is first freed from these associated minerals and impurities by mechanical treatment at the mines, and the concentrate, which contains titanium oxide to the extent of 4.5 per cent. is sent to the factory for treatment.

The first process in the manufacture is to reduce the concentrate to a state of fine powder by pulverisation in a ball mill. This powder is then mixed with concentrated sulphuric acid to the consistency of paste. On heating this mixture a violent reaction commences, which once started proceeds exothermically, with the result that the mineral is entirely decomposed and converted to a mass containing soluble sulphates of iron and titanium, which sets up into the form of a hard cake. This cake, or "coagulated mass," as it is technically termed, is then reduced to powder by means of a disintegrator and extracted with water, a solution being thus obtained of iron and titanium sulphates.

Owing to the fact that the salts of titanium are very unstable, it having, in fact, as much tendency to act as an acid as a basic radicle, on heating this solution nearly to boiling point for some hours, the titanium sulphate breaks down and titanitic acid is thrown down from the solution as a white precipitate leaving the ferrous sulphate in solution. By this ingenious means the titanium can be completely separated from the iron, all that is necessary being to subject the precipitate to a thorough process of washing.

Owing to the fact, however, that the precipitate of titanitic acid is in such an extremely fine state of division that it will pass through any filter cloth, the ordinary method of collecting and washing the precipitate by means of the filter press cannot be utilised, and the more costly and elaborate method of washing by decantation has to be resorted to.

If the pulp thus obtained after removing as much water as possible by this means is merely dried an amorphous product is obtained, consisting of titanium hydrate with a small proportion of acid sulphate of titanium and free sulphuric acid. This product does not form a reliable pigment as its opacity is not fully developed, and being a hydrate it is not perfectly stable in presence of organic bodies such as linseed oil.

In order to develop the physical condition required, the pulp is, therefore, passed into a rotary furnace of a type similar to that used for cement, where it is in one operation dried and calcined to a high temperature. By this means the titanitic acid is converted to anhydrous titanium oxide and changed from the amorphous state to a cryptocrystalline condition. The titanium oxide comes out of the furnace in the state of small friable nodules, which are finally pulverised and converted into an extremely fine powder by a process of air flotation.

The manner in which the calcination process is carried out is of great importance, and careful control is necessary. It is essential to carry it far enough to convert all the titanium from the amorphous to the crystalline condition, but at the same time it must not be carried too far, otherwise crystalline form as well as structure will be developed, which would ruin the product by rendering it gritty. The essential point is to change the internal structure of the particles without altering the size and shape in which they are precipitated.

It was found by experience, however, extremely difficult to control the reaction to this nicety on the large scale if a precipitate containing pure titanium was employed. In order to prepare the titanium pigment—which is known as "titanium white" to distinguish it from the pure oxide—further modifications in the process of preparation were found to be necessary. As a result of careful research on this point, it was found that by precipitating the titanium together with barium sulphate a physical

combination of the two is formed, which is more easily controlled on calcination than the pure oxide and, at the same time, is very much more economical to produce. It has been found that the most efficient combination of these two substances for most purposes is that containing equal equivalents of each, that is to say, one molecule of titanium oxide in combination with one molecule of barium sulphate or, by weight, titanium oxide 26.5% and barium sulphate 73.5%. Pigments containing a higher or lower percentage of titanium can, however, be produced at will.

In practice the pigment is produced in two strengths—one containing the two materials in the above proportions—roughly, 25% of titanium oxide, which is the standard product. The other, which is used for special purposes, contains a much lower proportion of barium sulphate, and the maximum content of titanium which can be satisfactorily used. To distinguish between these two varieties I will refer to them when necessary as standard titanium white and extra titanium white respectively. It will be noted that the large proportion of barium sulphate present, particularly in the case of the standard grade, is an essential part of the pigment and in no sense an adulterant as in the case of a mechanical addition of barytes. Such a mechanical mixture would not give the required properties. In fact, the purity and physical condition of the barium sulphate is of great moment in the production of these pigments.

Theoretically, one would imagine that the best way to form this combination would be to precipitate the titanium and barium simultaneously, but in practice there is a risk of bringing down some of the iron if this is done, and it is found preferable to form the barium sulphate first and add it in the state of pulp to the solution and precipitate the titanium on it by the process just described. After the combined precipitate has been washed free of iron and before it is transferred to the furnace, a small proportion of barium carbonate is added to it in order to insure that every trace of free sulphuric acid is neutralised by conversion into barium sulphate, as this would obviously be objectionable in the pigment.

The pigment as produced by this process in the early days was not quite perfect in colour, having a yellowish cast, which, at the time, was attributed to the fact that the

iron was not entirely removed. Thus, Coffignier, in his book, "*Couleurs et Vernis*," published last autumn, writing on titanium white, states as follows:—

"Le produit commercial est une poudre blanche, qui manque un peu de pureté car elle contient une très faible quantité d'oxide de fer," and he goes on to predict a great future for it if this objection could be removed.*

It was found, however, that after taking every possible precaution to free the product from the least trace of iron, it was impossible to prevent it turning slightly yellowish in colour during the process of calcination, and it was eventually discovered that the very natural assumption that this discoloration was due to a trace of iron was, as a matter of fact, absolutely incorrect. As a result of careful research, it was proved that it was due to a molecular change which takes place in the pigment during the process of calcination. By calcining the titanic acid to a sufficiently high temperature for a sufficiently long time, it is possible, in fact, to develop in it clearly defined rutile crystals of a distinctly yellowish colour.

The problem now arose how to prevent this change taking place, and this entailed a very considerable amount of research before the very simple remedy was discovered. If a small proportion of the titanium is present in the form of phosphate, the change is, for some reason which it is very difficult to understand, entirely prevented, and a perfectly white product obtained. This discovery has only been made comparatively recently, with a result that the pigment as produced to-day is vastly superior in quality. The prediction made by Coffignier is, therefore, already in course of fulfilment, the titanium white of to-day being remarkably brilliant and pure in tone.

Titanium white as thus produced has chemical properties which render it of the utmost value as a pigment, particularly for the preparation of protective paints. Owing to the fact that titanium oxide, like silica, is the most chemically stable compound of the metal, the pigment is extremely resistant to attack by any of the destructive agencies to which it is likely to be exposed. That it will resist the attack of sulphuric acid, which is notoriously the chief destructive agent in the air of our towns, will be readily

* Charles Coffignier, "*Couleurs et Vernis*," p. 55.

conceded when one considers that the pigment is actually produced in the presence of free sulphuric acid. Neither is it liable to discoloration by sulphuretted hydrogen because titanium does not readily form a coloured sulphide. Being also a fully oxidised body and in the crystalline state, it is not readily attacked by sea air or salt water, which are most severe upon pigments. One would, therefore, expect great durability from paints made with this pigment, and this point has been very carefully investigated on a most elaborate

I have had the opportunity of studying these tests minutely and examining in detail the methods of preparing the paints and the precautions taken to render the data obtained reliable. It would be tedious to attempt to give in detail the mass of information resulting from them. The general results may be summarised to the effect that the paints made with titanium pigment have shown no tendency to crack or peel, but have worn down evenly and uniformly, the surface finally becoming powdery ("chalking" as it is technically termed)

FIG 1.—General View of Exposure Tests of Titanium Paints at Fredriksstad

scale by means of the practical exposure tests, of which I now show you illustrations.

In these tests, paints made with every available white pigment in every possible combination have been painted on boards and exposed side by side since 1918. Information as to the effect of over three years' exposure is, therefore, now available, although, as a matter of fact, the conditions of exposure have been so drastic, the boards being exposed to a direct south aspect at an angle of 45° , that I consider the weathering effect is equivalent to at least five years of exposure under ordinary conditions.

and remaining in an excellent condition for repainting. As a matter of fact, the most durable paint of all proved to be that prepared from a combination of titanium white with a proportion of zinc oxide. One can readily understand that this should be the case, because owing to the complete chemical inertness of titanium it does not have any hardening action on the oil, so that paints made with pure titanium are inclined to be too elastic. The well-known hardening effect of zinc on the oil, has, therefore, the effect of giving the necessary hardening to the paint, provided it is added in moderation.

FIG. 2.—Detail View of Exposure Test Fence

Owing to the fact that titanium is not a definitely basic pigment like lead or zinc, but quite neutral in character, this complete inertness or lack of action on the vehicle with which it is mixed to form paint, is one of its characteristics, and for this reason it is rather slow drying in character. This is an advantage rather than otherwise, for some purposes, such as the preparation of artists' colours, but a disadvantage where the conditions of painting demand fairly quick drying, as in ordinary house painting. The preparation of paints from it which will dry in the reasonable time required by the decorator does not, however, present any serious difficulty in practice.

Owing to the chemical stability of this material, it is possible to use it for those methods of painting where none but the most permanent of pigments are admissible, such as true fresco painting, where the pigment has to stand the action of caustic lime. More important from the practical and economic point of view is the fact that on account of this chemical stability it is not readily absorbed into the system if accidentally inhaled or otherwise taken into the

body by the painter in the course of his work. In order to be so absorbed it is necessary for the pigment to be re-acted upon by the gastric or other juices and converted into soluble salts, and being practically unattacked by any such solvents it passes through the system without being absorbed. Even if we assumed that it could be so absorbed, however, it is generally conceded that the soluble salts of titanium are quite harmless. One may believe, therefore, with the utmost confidence, that this pigment is absolutely non-poisonous and harmless in use, a consideration of great practical importance at the present time. As a matter of fact, one of the unlooked for and somewhat surprising uses to which it has been put for this very reason is the preparation of cosmetics and face powders.

The physical properties of this pigment are, perhaps, even more interesting than its chemical properties; the most important from the practical point of view being its extraordinary opacity, which is greater than that of any other known white pigment. This fact is clearly demonstrated by the illustrations I now show you. It is a some-

FIG. 3 -- Test of Resistance of Titanium White to Corrosive Gases: Wall of Chemical Laboratory, originally painted uniform White, after two years' exposure. Ordinary White paint used *above* the line A B, paint made with Titanium White *below*.

what difficult matter to express such properties as opacity in terms of figures, but one is able to do so with a reasonable approach to accuracy by means of a little instrument recently invented by Dr. Pfund, whereby the thickness of a film of paint required to produce a definite degree of opacity can be directly measured.

By measuring in this instrument the opacity of paints made by grinding different pigments in oil in accurately determined proportions, using always exactly the same oil for the purpose, one can calculate the relative opacity of two or more pigments. Determined in this way, the opacities of the principal white pigment expressed as the relative *weights* required to produce equal obliteration of a surface, are as follows :

Extra titanium white	130
Standard titanium white	100

Zinc oxide	77
Lithopone	65
White lead	46
Basic sulphate of lead	35

It is, however, more practical to base the comparison on equal *volumes* of the respective pigments; expressed in this way the figures are quite different, owing to the difference between the specific gravity of the pigments, the figures obtained being as follows :—

Extra titanium white	140
Standard titanium white	100
White lead	88
Zinc oxide	77
Lithopone	66
Basic sulphate of lead	58

It must be admitted that this method of measurement is to some extent *academical*; the usual method adopted in practice

of comparing the opacity of two pigments being to make them into paint of equal consistency and paint them out over a black and white surface. Whilst I do not, therefore, lay too much stress on the above figures, the general result they show as regards the great opacity of titanium white is borne out by any form of practical trial.

The point that interests one most, however, in this connection is the *reason* for this remarkable opacity.

The opacity of any paint depends on the extent to which the light falling on it is reflected by the particles of the pigment in it instead of being allowed to pass through them and so reveal the surface beneath. This is largely influenced by two things. In the first place the smaller the size of the particles the more surfaces are presented for reflecting the light. But this by itself would be of little service unless each of these individual surfaces has a pronounced power of reflection, and the extent to which this is possessed depends on its optical properties and particularly the refractive power.

It will be seen from the accompanying table of refractive indices that that of titanium oxide is remarkably high, from which one would expect great opacity from it.

Selenium	2.92
Titanium Oxide, crystalline ..	2.71
Extra titanium white	2.60
Diamond	2.40
Zinc sulphide, crystalline ..	2.37
Zinc sulphide, amorphous ..	2.30
Standard titanium white ..	2.30
Sulphur	2.00
White Lead	1.99
Zinc Oxide	1.90
Titanium hydrate, amorphous..	1.80
Blanc Fixe	1.64
Barytes	1.63
Quartz	1.55
Linseed oil	1.49

I may say, with reference to this table that the refractive indices for the various pigments were determined by the microscopic method of making slides of the pigment immersed in a series of media, the refractive powers of which are accurately known. Mixtures of selenium and sulphur were used as immersion media for those pigments which range above 2.0, prepared according to the method adopted by the U.S. Geological Survey.*

It will be noticed as regards Titanium pigments that the method of preparation has an important bearing on this important property of opacity. During the course of the calcination process, which I have described as forming part of the preparation of the pigment, the titanium is converted from the amorphous to the micro-crystalline state, which has the effect of increasing the refractive power from 1.8 to 2.71. The extraordinary point is, however, that when the combined precipitate of titanium oxide and barium sulphate is calcined in this way the opacity of the composite product obtained is far above the mean of that of the two constituents. The theory put forward by Washburn to account for this is that on precipitation the titanium oxide forms a coating on the surface of the particles of barium sulphate. When the product is calcined and is changed from the amorphous to the crystalline state the result is that each particle of the pigment thus formed consists of highly refracting titanium oxide inter-crystallised with low refracting barium sulphate. By this means additional reflecting surfaces would be formed within each particle, and the reflective power, and consequently the opacity of the pigment thereby increased.

But I must confess that I do not know of any practical proof that this inter-crystallisation actually happens. I have made many endeavours to satisfy myself as to what really takes place, by microscopic examination, but have hitherto entirely failed to identify any definite structure of this nature. But whilst the actual cause thus remains a matter for further study, the practical fact is beyond dispute that a combination of titanium oxide and barium sulphate produced in this way has almost as great an opacity as the pure titanium oxide itself, although by itself the barium sulphate has such little refractive power as to be practically transparent in oil.

It is this high opacity which forms one of the most valuable properties of the pigment, and renders it of peculiar value for various special purposes where this quality is particularly desired, such as for the delicate hair lines of illumination work, the preparation of white printing inks and similar cases where it is required to produce an intense white colour on a dark background in one operation.

In addition to the refractive property of

* See *American Journal of Science*, Vol. XXXIV., July, 1912

the substance, its opacity is also influenced by the state of division. As mentioned in describing the method of preparation, the titanium oxide precipitate is so extremely fine in character that it cannot be filter pressed, which is a further reason for its exceptional opacity. It is, as a matter of fact, much finer than any other white pigment, the average diameter of the particles being no more than one micron.

But, to my mind, the most interesting point of all connected with the physical properties of this material is the fact that, combined with the remarkably high refractive index, it has a remarkably low specific gravity, as will be seen from the following table:—

Titanium white, extra	4.00
Barium sulphate.. ..	4.20
Titanium white, standard	4.30
Lithopone.. ..	4.30
Barytes	4.5
Zinc oxide	5.66
Basic sulphate of lead	6.41
White lead	6.81

In general, one finds that the refractive power of a substance is roughly proportional to its specific gravity. When, for instance, a substance is converted from the amorphous to the crystalline state the refractive power increases, and the change is generally accompanied by a corresponding increase in specific gravity. But if we compare, say, white lead with titanium white we find that whereas its specific gravity is considerably higher the refractive index is actually lower, although both are distinctly crystalline materials and one might, therefore, reasonably expect them to follow the same general principle as natural crystals.

It is suggestive, in this connection, to refer to the diagram published by Prof Miers in his lecture on "Precious Stones."* This shows clearly that the refractive powers of all the natural crystalline minerals used as precious stones are approximately proportional to their specific gravity, with two notable exceptions—the diamond and sphene, both of which have abnormally high refractive powers and exceptional optical properties generally. Now sphene contains approximately 40% of titanium oxide. The coincidence appears to me to be striking and confirms one in expecting the abnormal opacity of titanium oxide, which we find to be borne out in practice.

If we consider this exceptional combination of physical properties—the extreme opacity combined with the great lightness and fine state of division; if, further, we take into consideration the durability and stability resulting from the chemical composition of this titanium product, it seems clear that it has quite exceptional possibilities as a pigment, which, in my opinion, at any rate, justify one in thinking that it is destined to become one of the most widely used and one of the most valuable materials at the service of the painter.

At present it is in its infancy, and forms a fascinating subject for research on the many technical problems with which its production and utilisation is still surrounded.

I want, in conclusion, to say a little more about titanium oxide, as distinct from the pigment produced from it.

I mentioned in describing the extraction of titanium oxide from the ore that if the pure titanium precipitate were collected and dried it would not in this state form a very reliable pigment. But if this precipitate is washed and dried at a temperature only high enough to drive off most of the combined water an amorphous titanium oxide is obtained of the following average composition:—

TiO ₂	93.00
Combined water	3.25
SO ₃	2.75
SiO ₂	0.85
Fe ₂ O ₃	0.13

With the same plant used for the preparation of titanium white this practically pure titanium oxide can be readily produced in large quantities. The industrial utilisation of this product is still in the research stage. Considering the enormous stores of the raw material which nature has placed at our command, the fact that it is now available in a high state of purity in quantities which are only limited by the demand, the utilisation of this substance would usefully form a subject of investigation in many industries. I have in mind, for instance, the glass industry, in which it seems to me that titanium oxide has distinct possibilities. Research in this direction has, as a matter of fact, only been held back because no available supply was forthcoming. This restriction now being removed, I believe that titanium oxide will find uses in many unlooked for directions on account of its peculiar combination of properties.

* Prof. A. H. Miers. 'Precious Stones. Cantor Lectures, Royal Society of Arts, 1896.

DISCUSSION.

Mr. H. O. WELLER (Director of Building Research, Department of Scientific and Industrial Research), said that, in view of the work of the H.O. Departmental Committee on Industrial Paint Dangers in which he himself was engaged, he felt that he would prefer not to make any contribution to the discussion. He could only thank Mr. Heaton very much for his interesting paper, and say that if there was a rival to white lead, he thought it was titanium oxide. He had had the pleasure of hearing Professor Jehsen give an account of his process.

SIR THOMAS H. HOLLAND, K.C.S.I., K.C.I.E., D.Sc., F.R.S., said that he had no ideas at all upon the subject, unlike the last speaker, who had too many. Nor had he any interest at all in any form of paint; he had much more interest in the mineral which had to be utilised in order to give rise to this product. But the paper was one of extreme interest. Mr. Heaton had drawn attention to the fact that titanium oxide was very widely distributed throughout the globe. If an element was very widely distributed, considerable difficulty often arose from its wide affections. It would associate with a very large number of other elements, and it was very difficult to dissociate it. The reason why it was widely distributed was also the reason why it was difficult to separate. Titanium was, indeed, widely distributed; in fact, it was a perfect nuisance in many economic processes, especially in iron smelting; and on account of the similarity of its properties to those of the elements with which it was associated, it was as difficult to separate as alumina from silica. Hitherto, it had been one of the greatest drawbacks that it was difficult to obtain titanium oxide in a pure form at a price that would make it useful for many applications in the arts. This difficulty, so far as it was technical, had been got over, but there still remained the economic question, and he was rather glad that Mr. Heaton had not introduced into his paper any estimates as to the cost of production, for this must be an expensive process. For one thing, it was obvious that the more iron ore that was left in the crude material, the more sulphuric acid would be wasted in the subsequent process of treatment. Then there followed a whole series of processes, all of which were more or less expensive. The product, therefore, was likely to be costly. Mr. Heaton, however, had then touched the spot very cautiously, but he thought very definitely, when he pointed out that here was a product of large volume for a small amount of weight, a high degree of opacity, and, obviously, lasting qualities, which must be out of all comparison with the products which had had to be used

hitherto for white paints. As an officer who happened to be responsible during the war for keeping in condition a large fleet of ships, and a still larger number of railway carriages, he realised how difficult it was to get a reliable paint seller! It was difficult to be sure that one was getting the product one paid for; but here was a product so obviously valuable that there was no doubt the chemists would soon get to work and prepare methods for the detection of adulterants, which would be the first industry that would spring up when this product got fully into operation. The paper had been of the greatest interest from the technical and scientific point of view.

Mr. WALTER C. HANCOCK said that Mr. Heaton had proved practically conclusively that titanium oxide was from its very nature one of the most suitable materials that could be found as a pigment. Titanium was a most extraordinarily widely spread material. Titanium oxide was extremely resistant in its action to other reagents, and in addition to its use as a pigment, it had several possibilities in application to which Mr. Heaton had alluded. The fact that titanium oxide in a very pure condition could be obtained commercially at, he took it, a reasonable price, would be welcomed by the people who were interested in the production of enamelled ware. It was one of the most useful opacifying agents available for this purpose, and was used in a good many cases for ceramic work. Mr. Heaton had also referred to the utilization of titanium oxide in glass manufacture. He fancied that Mr. Heaton had at the back of his mind the idea of a substitution of a large proportion of the actual silica in an ordinary silica glass by TiO_2 . But the speaker would like to bring to his notice the fact that some time ago a patent was taken out—he believed in France—for the production of a material known as siloxide, prepared by fusing together a relatively large proportion of silica with a small proportion of some refractory oxide, of which two were suggested—namely titanium oxide and zirconia. The properties of the resulting material were remarkable. It was extraordinarily resistant chemically, and he believed thermally, and could be worked comparatively easily, much more so than the ordinary fused silica ware. He could endorse Sir Thomas Holland's remark that titanium was a nuisance in some respects. On the other hand, he believed the melting point of pure titanium oxide to be about $1,400^\circ \text{C.}$, so that if titanium oxide was procurable in suitable quantities, it was quite possible that amongst its other applications it might be used for certain refractory purposes with the limitation that refractoriness was not required beyond about $1,400^\circ \text{C.}$ From the development of this and kindred processes, he thought the industrial world might reap considerable benefit.

MR. J. CRUICKSHANK SMITH thought that many interesting points had been brought out. In the first place, he was glad to hear Mr. Heaton acknowledge so frankly the origin of much of the work he had brought before them that evening. A paper was read on this same subject about a year ago at the Paint and Varnish Society, and those who had listened to that paper recognised the inspiration of many of the statements made that evening. With regard to the subject of titanium white, he was only interested in it from the point of view of industrial painting. In industrial painting every white pigment was of interest. Nearly nine-tenths of painting work was carried out by means of white pigments, and of the nine-tenths a very small part was done by professional painters—that is, craftsman painters. Most of the paint was put on by more or less unskilled people. This made it all the more important that every new pigment which was discovered and developed should be brought to the notice of the public at large. The pigment which Mr. Heaton had been telling them about that evening was a most important one. In the first place, it was not what was so commonly and glibly called a "pure" pigment. It contained a notable quantity of so-called adulterant—namely, barium sulphate. In analyses and specifications of paints and pigments one often found imposing specifications aiming at so-called purity. Now, the thing which was not wanted was purity. What was wanted was a conglomeration of properties to give a definite result. This was given by titanium white. He believed that there was a great future for such a pigment, and for two reasons. In the first place, it was not a basic pigment, therefore it had not the action upon oils and other materials which was customarily associated with such pigments as white lead and oxide of zinc. In the second place, this pigment possessed great opacity. He noticed, by the way, that in the composition of the amorphous titanium oxide obtained after the precipitate had been washed and dried at a temperature only high enough to drive off the combined water a considerable proportion of SO_3 (2.75 per cent.) remained. Was it not possible to eliminate that impurity in the course of the production of the material? He thanked the author for a most admirable and suggestive paper.

MR. CHARLES HARRISON said that he had listened with great interest to Mr. Heaton's lecture, and he thought that the paint and varnish trade would welcome his remarks on their publication in the *Journal*. This titanium white was an exceptional pigment. He could bear out what Mr. Heaton had said; in fact, he had himself been making a few notes concerning this pigment. He agreed with Mr. Smith that the general public should be let

into the secret a little more, and he also seconded his remarks on the question of purity. An analysis which showed purity did not mean that the pigment was a good one. In fact, the mere analysis might tell one nothing. He wished to suggest a few warnings. In the first place they must not consider that titanium white was a substitute for white lead or zinc oxide or lithopone; conversely, white lead was not a substitute for titanium white, nor for zinc oxide. He had found by experience that this titanium white was an inactive pigment in the chemical sense. It was a permanent white pigment, also the most opaque of white pigments. It was an accelerator of white pigments—which might be a useful property. It was unchanged by linseed and other drying oils in the passage to their solid products. It was without drying properties; was unchanged by dull red heat; also was inactive in any kind of varnish—oil or methylated spirit varnish. It was inactive to all coloured pigments; coloured pigments would not interact with it. It was a suitable pigment base for aniline dyes. Finally, if zinc oxide was a so-called non-poisonous pigment, then titanium white was more than its equal in this respect. Neither of them was edible! And the dust of neither should be inhaled. He believed that titanium white would be found to be one of the best of pigments when employed with common-sense.

MR. JOHN D. BATTEN said that he could only speak as a painter of pictures, but, of course, this was just the pigment painters were wanting. They had had the demerits of white lead pointed out to them, and, indeed, had experienced them; and zinc white had not filled the place. He was full of hope that Mr. Heaton would succeed in giving them the strong white pigment they were wanting in every kind of picture painting.

MR. F. DAKIN said that experience seemed to show that titanium white was very slow in drying. Was it possible for it to dry more quickly, and, if so, what drier should be applied to attain that result? With regard to its resistance to water, could wood or other similar substances be painted with titanium paint alone, without using a white lead undercoating? Was there any advantage to be obtained by mixing a certain proportion of white lead with titanium paint instead of zinc oxide, or with zinc oxide? It seemed to him that the addition of zinc oxide would have a tendency to make it less resistant to water. No mention had been made of another new pigment derived from antimony. He hoped that the lecturer would be able at some later date to give them some information as to antimony oxide for use as a pigment.

MR. BRUCE ANDERSON expressed his thanks to the reader of the paper, and hoped that Mr. Heaton would supplement his remarks by stating whether this titanium white could be employed as a useful basis for coloured painting work. He described a successful experience with a somewhat similar paint for use as a basis on the ironwork of gasometers.

MR. J. A. GIBSON said that he had come to the meeting as one keenly interested in the discovery of some material which should take the place of white lead, and if all was true that Mr. Heaton had told them about this material, he believed it would replace white lead in the painting trade and in this way avert considerable suffering. For this they had cause to be extremely thankful for the research work done in the laboratories. Although the production might be in its infancy and its cost considerable, the advantages of its volume and opacity had to be reckoned with, and these would go far to counterbalance the question of cost. He felt quite sure that with time the material could be perfected. Could Mr. Heaton give them any idea as to the amount of this material which might be produced from the ore available in this country? Also, as the question of opacity was of great importance it would be of interest to many of them to know how many coats would have to be put on in order to get the opacity shown in the specimen boards which the lecturer had exhibited.

THE CHAIRMAN, before calling upon Mr. Heaton to reply, said that he had always understood that in the German chemical trade they tried any new product first for one purpose and then for another, and if they could find no other use for a substance they put it forward as a patent medicine! The fact that this material had absolutely no effect upon the human body would seem to make it all the better for this purpose.

MR. HEATON, in reply, said that he considered the various speakers had been very generous in their remarks on his paper. Sir Thomas Holland had raised the question of the cost of production. That was a question which he purposely did not touch on, because he wanted to confine himself to the more technical and scientific side of the subject. But he might say that, as a commercial proposition, the speaker was perfectly correct in his suggestion that, in spite of the fact that the price per hundredweight of titanium white was comparatively high, it was actually more economical in use. This was accounted for by its properties, particularly its lightness and extraordinary opacity. Mr. Hancock had suggested what he himself was thinking of in connection with the glass industry, that

here they might have to some extent a substitute for silica. Also, as Mr. Hancock said, it was rather a point in its favour that it might be used in the production of refractory materials owing to its extraordinarily high melting point. With regard to the remarks of Mr. Cruickshank Smith as to the content of barium sulphate, he thought that what Mr. Smith desired to point out was that whereas in many cases the analysis would report that barium sulphate was present in a paint, and, therefore, it would be assumed that it was an adulterant, as a matter of fact, the exact contrary might be the case, and the barium sulphate be, not an adulterant at all, but an integral part of the pigment. This was true of other pigments besides titanium white—lithopone, for instance. The barium sulphate was not added as an adulterant; it was an essential part of the pigment itself. When he used the term "barium sulphate," he meant the artificially produced barium sulphate, and not the natural product which was in crystalline form. With regard to the presence of sulphuric anhydride in the pure titanium oxide, he did not think that this was an impurity of any moment, for the purposes for which the material was likely to be used. He would emphasise, however, the fact that this impurity was carefully eliminated in the case of the pigment, which was quite another matter. Mr. Harrison and other speakers had referred to the fact that titanium oxide was not to be considered as a substitute for lead and other pigments. He desired to make it clear that the scope of his paper was confined entirely to the preparation and properties of titanium pigments—a discussion of the relative merits of different white pigments would be quite irrelevant to this purpose, and he had refrained from mentioning any other pigment, except where this was absolutely necessary in order to give some idea of the properties of the pigment with which he was dealing. Mr. Dakin asked about the slow drying of titanium; that certainly was a point to be considered. It was slower drying than white lead, but there was no difficulty in overcoming that, and the most efficient drier he had found was a combination of lead and cobalt. He had also asked whether titanium could be used as an undercoating. He wanted it to be understood that all the exposure trials to which he had referred in his paper were straight trials; the same mixture was used throughout, and the tests went to prove that it could be used all the way through, from beginning to end of the painting. Mr. Dakin had asked whether it would be of equal advantage to mix titanium with white lead instead of zinc oxide. Experience had shown that that was not the case. The combinations of titanium white with white lead did not show up nearly so well as the combination of titanium with a small pro-

portion of zinc. That experience had been confirmed in America by the Institute of Industrial Research, which published a report on that very question. This report would be found in the *Bulletin* of the Paint Manufacturers' Association. The investigators came to the same conclusion, that the mixture with white lead was not effective, whereas the mixture with zinc oxide was valuable. With regard to the supply in this country, it would be governed by the demand, and be equal to the demand. As regards the opacity, the specimens exhibited had been painted with only one coat over the black line.

The proceedings concluded with a cordial vote of thanks to the author of the paper

NOTES ON BOOKS.

METRIC SYSTEM FOR ENGINEERS. By Charles B. Clapham. London: Chapman and Hall, Ltd., 1921 12s 6d net

Well meant efforts to simplify, improve or supplement our statutory metric system may be largely responsible for the existing undercurrent of opposition; moreover, the numerous "simplifications" by many writers have, in the aggregate, led to a notable degree of complication. We, however, suggest that the spirit of the tacit *Contrat Social* of Rousseau should inspire writers of books and public teachers, to respect details and forms as embodied in our national laws. At any rate, writers on the metric system would do well to verify all their data by reference to the official printed copies of statutory documents, instead of taking the too usual course of copying from other books or from the manifestos of associations or congresses.

Mr. Clapham is transparently straightforward and candid in considering the arguments for and against the metric system, and is evidently desirous of realising the utmost accuracy in every detail; moreover, he is lucid, thorough and careful in his workshop details; therefore, the book may be cordially recommended to the engineering community, notwithstanding the many departures from statutory terms or conditions, but these inconveniences may be eliminated in a second edition.

Uncertainty and redundancy centre largely on abbreviations, some 72 being tabulated on p. 5. Of these, Mr. Clapham favours or adopts 35 and rejects 37, the statutory abbreviations (grm.) for gramme being among those rejected; he prefers the shortened form g., but he expands the customary cc. to cu.cm. The present statutory spelling "gramme" for the primary unit of weight is rejected by our author (p. 3), who declares in favour of "gram," a form adopted in the Act of 1878 by its 3rd

schedule, but it having been found that grain and gram may be so similar if hastily written as to involve danger in the matter of medical doses, the full spelling was restored by the Act of 1897, with its two supplements, Statutory Rules and Orders Nos. 410 and 411. On p. 67, Mr. Clapham states that the centilitre and the millilitre are superseded by the cubic centimetre; but the last mentioned Act of Parliament is against him, as it abolishes the cubic centimetre as a measure of capacity and replaces it by the nearly equivalent millilitre.

As our author touches lightly (p. 141) on the origin of a decimal basis for weights and measures, it may be mentioned that our old Roman system is decimal in its origin, like the more recent French metric system. Thus our mile is decimal in origin, and in name (*mille passus* or *mille passuum*); the steps being complete or 2-phase steps of 5-feet, but our mile appears to be nearly 100 yards over measure. In Rome, as here, the decimal mile was soon divided by repeated halvings: just as in France the pedestrian thinks, speaks and writes of quarter kilometres. Our gallon after many changes, appears now to be very near to the standard of the old Roman ten-pound gallon. Thus, our gallon of water weighs ten pounds, or 70,000 grains, and by repeatedly halving the pound of 7,000 grains, we arrive at the ounce of $437\frac{1}{2}$ grains. Thus our avoirdupois ounce is not a strange unit chosen in a fit of mental alienation, but an example of the arithmetical complication which may result from repeated halving.

Vitruvius, who wrote his *De Architectura* about two thousand years ago, mentions the early use of ten as a basis, the reasons for favouring ten, and also Plato's advocacy of ten. Subsequently Vitruvius refers to a period when his own people (the Romans) somewhat revived decimalism by establishing a denarius consisting of ten asses, but soon there was a new unit from the denarius by quartering and thus was formed the sestertius of $2\frac{1}{2}$ asses. (Vitruvius, Lib. III. Cap. I. pp. 57 to 60 of the Tauchnitz 1828 stereotyped edition) The sequel is touched on in Dr. Smith's *Students' Latin Grammar*, London, 1863. Appendix IV. pp. 363-364. We here read of the building of an elaborate new decimal system on the basis of the sestertius, which, in the later time of the Republic, became the unit of business calculations. The above mentioned cycle of change, decimalism, quartering, new decimalism, appears to be usual.

Considering facts and tendencies as history shows them, the suggestion made by that eminent engineer, Sir Frederick Bramwell, in a letter to the *Times* of March 20th, 1899, may be worth mention. As regards our two systems (Roman and French), he says "Let the two exist together and experience will prove which is the one preferred by the community."

OBITUARY.

WILLIAM NEWTON BEST, M.Am.S.Mech.E.—The death took place on April 11th, of Dr. William Newton Best, of New York City, who was elected a Fellow of the Royal Society of Arts in 1915.

Dr. Best was born in Quincy, Ill., in 1860. He became president and consulting engineer of the well-known firm, W. N. Best Furnace Burner Corporation, Broadway, Manhattan, and owned over 40 patents for inventions for burning oil for heat and in manufacturing plants. Sixty-five per cent. of the furnaces burning oil for refining glass, steel and other metals throughout the United States, are using burners that he invented.

Dr. Best was a member of the American Society of Mechanical Engineers, the American Institute of Mining and Metallurgical Engineers, The American Institute of Metals, and the American Railway Mechanics Association. A man of wealth he was a generous supporter of many Brooklyn and other charities.

GENERAL NOTES.

BITUMEN IN PALESTINE.—Bitumen is gathered in Palestine from the Dead Sea, where it is found floating on the surface of the sea. Prior to the war this bitumen was gathered and turned over to an American, who lived in Jerusalem, who in turn exported it by special permit. It is said that the annual export amounted to approximately 50 tons, and that practically the entire output was sent to Germany, where it was used in preparing the gloss for patent leather. At present, writes the United States Assistant Trade Commissioner at Constantinople, very little of this bitumen is being gathered, but it is possible that by using dynamite or other depth charges, large quantities might be obtained out of the Dead Sea.

OIL SHALE IN PALESTINE.—On the shores of the Dead Sea and west of that sea, between Jerusalem and the vicinity of Nebi Musa, is found a peculiar stone. The stone, which is abundant, is commonly used by the local people in making souvenirs. It is a matter of common knowledge, reports the United States Assistant Trade Commissioner at Constantinople, that the Bedouins have used this stone for several years as fuel, and it is reported that during the war it was so used by the Germans. It is said that the latter also extracted oil from it. The stone is called Dead Sea stone and Stinkstein. In the Yarmouk Valley in Northern Palestine are also found vast quantities of an oil-impregnated shale. When burned this shale leaves a very fine quality of lime, which, when air slaked, is said to be very superior for building

purposes. It is reported that during the war the Germans extracted oil from this substance by baking.

NEW KNOCKDOWN SAFETY PACKING CASE.—A new knockdown packing case has been placed on the market in Sweden, writes the United States Consul at Gothenburg, which the inventor claims cannot be opened and put together again without detection, as the lock can be protected with a seal which must be broken before the box can be opened in the proper way. The seal is protected by a metal lid, which prevents accidental breakage. It is also stated that the packing case can be taken apart in one or two minutes and can be used over and over again. The case is said to have been patented in 14 countries.

PRODUCTION OF ALSATIAN POTASH.—The production of Alsatian potash during the year 1921, writes the United States Commercial Attaché in Paris, shows a considerable decrease as compared with 1920, as noted by the following figures: Crude salt—1913, 355,341 metric tons; 1918, 333,500 tons; 1919, 591,571 tons; 1920, 1,203,000 tons; 1921, 895,744 tons; pure potash (K₂O)—1913, 58,000 metric tons; 1918, 55,700 tons; 1919, 98,000 tons; 1920, 192,480 tons; 1921, 146,355 tons.

MEETINGS OF OTHER SOCIETIES FOR THE ENSUING WEEK.

- MONDAY, JUNE 26.** Geographical Society, 135, New Bond Street, W., 8.30 p.m. Mr. R. A. Frazer, "The Oxford Expedition to Spitzbergen, 1921."
British Architects, Royal Institute of, 9, Conduit Street, W., 8.30 p.m. Presentation of Royal Gold Medal.
Faraday Society, at the Chemical Society, Burlington House, Piccadilly, W., 8 p.m.
1. Prof. A. W. Porter, "The Law of Distribution of Particles in Colloidal Suspensions, with special reference to Perrin's Investigation."
2. Mr. W. R. Cooper, "The Electrochemical Effects Produced by Super-imposing Alternating Currents upon Direct Currents."
3. Prof. T. M. Lowry and Mr. E. E. Walker, "Properties of Powders, Part II. Expansion and Shrinkage during Caking of Potassium Carbonate."
4. Prof. T. M. Lowry and Mr. L. P. McHutton, "Properties of Powders, Part III. The Powdering of Minerals by Decrepitation."
5. Dr. A. M. Williams, "Two Properties of Powders."
6. Dr. J. L. Haughton and G. Winifred Ford, "A Note on the Systems in which Metals Crystallise."
7. Mr. A. J. Kieran, "The Electrical Conductivity of Hydrochloric Acid and Potassium Chloride in presence of Sucrose."
British Academy, at the Royal Society, Burlington House, Piccadilly, W., 5 p.m. Mrs. Eugenie Strong, "XVII. Century Sculpture in Italy in its relation to Classical Art."
- TUESDAY, JUNE 27.** Colonial Institute, Hotel Victoria, Northumberland Avenue, W.C., 4 p.m.
Anglo-French Society, Scala House, Tottenham Street, W. 8.15 p.m. M. Maurice Thiéry, "Le Théâtre de Le Fiers et Callivet."
Anthropological Institute, 50, Great Russell Street, W.C. 8.15 p.m. Prof. A. Mawer, "The Study of English Place-Names."
- WEDNESDAY, JUNE 28.** Geological Society, Burlington House, Piccadilly, W., 5.30 p.m.
- THURSDAY, JUNE 29.** Royal Society, Burlington House, Piccadilly, W., 4 p.m.

NOTICE.

ANNUAL GENERAL MEETING.

WEDNESDAY, JUNE 28TH, 1922. MR. ALAN A. CAMPBELL SWINTON, F.R.S., Chairman of the Council, in the Chair. The One-hundred-and-sixty-eighth Annual General Meeting of the Society was held for the purpose of receiving the Council's Report, and the Financial Statement for 1921, and also for the Election of Officers and new Fellows.

A full report of the Meeting will be published in the next issue of the *Journal*.

PROCEEDINGS OF THE SOCIETY.

TWENTY-SECOND ORDINARY MEETING.

WEDNESDAY, MAY 10TH, 1922.

SIR MARTIN CONWAY, M.A., F.S.A., F.R.G.S., in the Chair.

The paper read was :—

THE DESIGN OF REPEATING PATTERNS FOR DECORATIVE WORK.

By MAJOR PERCY A. MACMAHON, R.A., LL.D., Sc.D., F.R.S.

During the last fifteen months, researches have been in progress concerning the division of flat space into identical figures. These have been undertaken entirely from a scientific point of view, because it became necessary to explore this field of thought in a thorough manner as a preliminary to the study of the corresponding division of space of three dimensions which is required in the treatment of crystallography, crystal structure and the structure of the atom. In scientific work, analogy is a guide which never fails, and it was realised that the experience gained in a compre-

hensive study of repeating patterns in two dimensions would be of inestimable service in the treatment of the far more difficult questions that arise in the solid theory. Before the investigation commenced, pains were taken to ascertain the present state of knowledge of the subject. On the mathematical side, a search was made among the contributions that have been made from time to time by geometers. These might have been more important than they have proved to be because the theory of the design is the proper business of the mathematician, and not of anyone in any other walk of life. Similarly, on the side of Art, the current Art text books were consulted, and other literature, including several lectures upon the subject, or very near to the subject, that have been delivered before this Society. Art libraries were requisitioned and yielded much information, and many designs purporting to be faithful copies of ancient and modern decorative work.

The search for the possible shapes of repeating patterns was then commenced, without any particular reference to any application that might be made of results to decorative work, and without any pretence of evolving decorative principles.

The object of the work was simply the partition of flat space into identical shaped areas or sets of areas.

One exception may be noted to the above statement. It soon became evident that the mathematical work leads naturally and easily to the special study of patterns which possess some kind of symmetry; and that a calculus can be invented which results in some rules for the construction and classification of symmetrical patterns which may be of special interest to those who, in industry or art, look with favour upon the use of repeating patterns.

Generally speaking, the progress made has resulted in the classification of all

repeating patterns into species, families, genera, etc., just as in the case of botanical specimens.

Repeating patterns have been found to be of service in industry and art throughout the ages, and the object in view in making this communication to the Royal Society of Arts is to bring to the notice of those who are concerned with the practical use of patterns the results that have been arrived at for scientific purposes; because, though possibly they may be found to exert no useful practical influence, yet designers may be at any rate interested in what the mathematicians have been discovering for their own purposes.

In short, the paper is solely concerned with the theory of the shape of the repeating pattern, and has not necessarily any connexion with the way that such patterns may be applied to practical use or to decorative schemes.

As I have explained elsewhere* the scientific principles upon which these patterns can be constructed and classified, I do not propose, in the short time at my disposal, to go into them here in great detail. I intend, after a short preliminary account of the theory, unburdened by the full particulars that are necessary to make the story complete, to shew some of the results upon the screen, and to dwell upon special features that may be new to the audience.

A repeating pattern is understood, in this paper, to be a figure of such a shape that a number of them may be fitted together so as to cover flat space without overlapping, and without leaving interstices.

Any number of separate figures fixed in relative position, which possess the same property, are included in the definition.

The only regular polygons which are repeating patterns are the triangle, the square and the hexagon. These were known to the ancients. Other patterns derived from them have been constructed upon various principles. The Moorish architects were very successful in their use, as is shewn in the decorations of the Alhambra at Grenada, and the Alcazar at Seville. But there has been little co-ordination. The subject is so extensive that this paper deals almost entirely with symmetrical patterns. They can only be satisfactorily studied by taking account of those which are without symmetry, which form

the scaffolding of the structure, and, finally, disappear. The method of study will now be introduced by the consideration of the simplest repeat, the equilateral triangle. This form differs from the square and the hexagon in one important respect. When we assemble the triangles, side by side, we find that they appear necessarily in two orientations or aspects. This is not the case with either the square or the hexagon, which, when assembled, present only one aspect. The bearing of this remark will appear later.

We commence by dividing the triangle into three equal parts by lines joining its centre with the angular points.

We now number the compartments of the triangle 1, 2, 3, always in counter clock wise order, and for convenience regard these numbers as denoting three different colours. The triangles, being coloured in the same manner, have still the fundamental property of being identical. We now propose to assemble these triangles in such wise that a certain law of contact of colours between adjacent compartments is in evidence. The most obvious law is that which insists that adjacent compartments shall be similarly coloured. Such an assemblage is shewn in Fig. 1, and it is clear that the construction can be extended indefinitely. The diagram establishes that the coloured triangle is a repeating pattern, and, moreover, one of a new kind because the assemblage is subject to a particular condition of colour contact. This contact, in respect of the triangular base, we call the First Contact System.

We may now denote it by 1 to 1, 2 to 2, 3 to 3, or, shortly, by 11, 22, 33.

FIG. 1.

FIG. 2.

In the case of the triangular base one other Contact System is possible, because we may take as the condition of assemblage, that one compartment, say that coloured 1, shall be adjacent to a compartment also coloured 1, while a compartment coloured 2 shall be adjacent to one coloured 3.

This is the contact system 1 to 1, 2 to 3, or shortly 11, 23. The assemblage, subject to this condition, is established by fig. 2, which can be indefinitely extended.

This system again gives us a new repeating pattern. Looking at both contact systems, we notice that the colour contacts are of only two natures. Adjacent compartments are either similarly or differently coloured. In each of the two cases the "repeat" is an equilateral triangle involving three colours. We now seek to transform the triangle, by connecting colour with shape, into a piece of another shape which is uncoloured. Consider the compartments coloured 1. The external boundary of each is a straight line which joins two angular points. How can we alter this boundary so that it will still fit into the similarly altered boundary of another compartment coloured 1? If we can do this it is clear that we can get rid of the colour and rely upon the altered shape of boundary to determine mechanically and automatically the same condition of assemblage as arises from the contact system affecting the colour 1.

FIG. 3.

Fig. 3 shews a simple way of effecting this transformation. A certain zig-gag boundary of the compartment leaves each triangle of the same shape and they fit together automatically. It is seen that the new boundary is constructed by adding and subtracting a certain area from the triangle and that the contours which determine the added and subtracted positions are in point symmetry with regard to the mid-point of the original straight line boundary between the compartments. In other words, each contour is the point-image of the other with respect to the said mid-point. The practical result of the construction is that the new boundary between the points A, B, is unchanged by rotation through two right-angles about the mid-point of AB.

This is exactly what is wanted so as to ensure that the triangles may be altered in the same manner, and fit together. In general we effect the transformation from colour to shape by taking any system of closed contours exterior to the original boundary as determining portions to be added to the triangle and a corresponding system of closed contours inside the boundary as determining portions to be subtracted from the triangle; the condition being that the latter system of contours must be the point-image of the former system with respect to the mid-point of the original boundary. The new shape or pattern then effectively replaces the colour. Subject to certain conditions in regard to the areas within which these systems of contour may be drawn, so that they may be compatible with other transformations connected with other colours, the designer has a free hand, and is in no way restricted to the use of drawing instruments. Examples of transformations of this kind are shewn upon the screen.

FIG. 4

They are of two different types. One which is symmetrical about the straight line perpendicular to the original boundary at its mid-point is said to be of type s_1 . One which is unsymmetrical about the same line is of type v_1 . Here the suffix has reference to the first nature of contact between colours. A transformation which is the optical reflection of a v_1 , in a line perpendicular, to the original boundary, though one extremity is denoted by iv_1 , a notation which is of much service when the design of symmetrical patterns is in

view. In order to avoid mutual interference of transformation patterns, we will for the present regard such patterns as restricted to lie within the rhombus found by the coloured compartment and its reflexion in the boundary. It will be found later that under certain circumstances this restriction may be much modified.

When we are dealing with the First System of Contact, each coloured compartment is separately transformed upon the principle above set forth with the result that we obtain a repeating pattern which replaces the coloured triangle. It will be observed that, following the rules of construction, these repeating shapes can be obtained in infinite variety. When the three colours differ from one another three different transformations enter into the construction of the pattern. If the colours described by 2, 3, be identical (so that for 3 we write 2) and different from the colour 1, two different transformations will enter; while if the three colours be alike (so that we write 1 for both 2 and 3) only one transformation enters and is applied to each of the three compartments. We have therefore the three cases, examples of which are shewn upon the screen. We have here the first part of a classification.

FIG 5

It will be observed that the repeating patterns, obtainable by transformation from the triangular base, are broadly speaking of three natures. Some are continuous within a single boundary line or contour. Others are discontinuous within a single external contour, differing from those which are continuous by exhibiting gaps or windows within the contour. Others consist of two or more separate figures relatively fixed in position. These it is convenient to term block, stencil and archipelago repeating patterns respectively. It will be observed too that some patterns partake of both stencil and archipelago characters.

The three natures specified occur in the case of all bases and all categories belonging to them.

We pass now to the Second Contact System 1 to 1, 2 to 3, which involves a contact of the second nature, because 2 to 3 specifies a contact between different colours.

If we make any new pattern or shape to

replace the colour 2 the new pattern to replace the colour 3 is thereby determined because the two pieces have to fit into one another. We have to find the geometrical relation between the two patterns.

FIG. 6.

In the diagram, Fig. 6, the colour 2 is replaced by an unsymmetrical zig-zag shape and this determines a corresponding but different zig-zag shape to replace the colour 3 in order that the two pieces may fit together when rotated in the direction of the arrows. This fitting necessitates the part added to the piece in the case of the colour 2 being the point image of the part subtracted from the piece in the case of the colour 3 and the part subtracted in the case of the colour 2 being the point image of the part added for the colour 3. To carry this out we suppose the triangles superposed and the images taken with respect to the mid-point of the original boundary.

We generalise this theory by taking, to replace the colour 2, any system of closed contours to determine additions and any system to determine subtractions from the piece; and then, to replace the colour 3, we take systems of contours the point images of the former as above explained. Patterns of infinite variety, subject to conditions that may present themselves, may thus be drawn and effectively replace the colours. Examples of transformations of this nature are shown upon the screen—Fig. 7.

FIG. 7.

For the purpose of a symmetrical calculus they are separable into three types.

One which is symmetrical about a straight line perpendicular to the original boundary through its mid-point is said to be of type S_2 , the suffix 2 having reference to the second nature of contact. If this refer to the colour 2, that for the colour 3 is denoted by PS_2 .

One which is unsymmetrical about the straight line above specified and is also unsymmetrical, as regards contours, about the original boundary itself is said to be of type U_2 , while the corresponding transformation for the other colour is denoted by PU_2 .

One which is *only* symmetrical as regards its contours about the original boundary line is said to be of type V_2 , and that for the other colour is denoted by PV_2 .

We have also a pattern IV_2 .

It will be noticed that

PV_2 is equivalent to IV_2 , a circumstance of great importance to the symmetrical calculus.

We have only one species of pattern, as shown in Fig. 8,

FIG. 8

the colours 2, 3 being transformed as above and the colour 1 by any transformation which appertains to the first nature of contact.

Repeating patterns based upon the equilateral triangle may be symmetrical about a line in the plane which bisects one of the angles. To secure symmetry we take transformation patterns for the sides containing the angles, one of which is the reflexion of the other. These patterns may be S_1 and S_1 , or U_1 and U_1 , when the compartments to be transformed are of the same colour, and V_2 and PV_2 ($=IV_2$) when the compartments are of different colours. A second kind of symmetry is about an axis perpendicular to the plane through the centre of the triangle. The symmetry is then triangular and can be secured in only one way, viz., by transforming each compartment according to the same pattern. This is only possible when the three compartments are of the same colour. In the subjoined classification (Fig. 9) the letters T.E. stand for Triangle Equilateral. The numbers (i), (ii) have reference to the contact

system which governs the assemblage and the transformations. The letters a, b, c, ... refer to the particular colour scheme of the compartments.

FIG. 9.

We have thus five categories of symmetrical repeats, some examples of which are thrown upon the screen. Each category involves an infinite number of repeats. Other bases are treated in a similar manner. Such include the isosceles triangles whose vertical angles are 90° and 120° , the square, rectangle, parallelogram and rhombus; the regular hexagon and some special hexagons and a special pentagon. These have been found particularly suitable and practically certain to include all repeats that are likely to be met with or to be of practical service. The details of these various species, though they have been worked out, cannot be given here, and I must content myself with showing some typical results later in the evening.

An interesting stencil repeat, based upon the triangle, which has a circular external boundary is now illustrated.

FIG. 10.

It is the result of applying the S_1 transformation (shown by its side) to each of three compartments of the triangle. It will be noticed that the transformation is not restricted to lie within the rhombus, to which reference has been made, but still there is no interference or incompatibility.

Circular repeats can be constructed in an infinite number of ways. Another is illustrated in which the triangle base has entirely disappeared as a result of the

FIG. 11.

transformation applied to each side. The reader will have no difficulty in discovering the S_1 transformation that has been employed.

All repeats based upon the equilateral triangle must exhibit when assembled either two or six aspects. One category (that to which the helmet pattern which has been shown belongs) can always be assembled in two distinct ways so as to show either two or six aspects at pleasure.

The transformation that has been explained is in principle applicable to all bases. It may be regarded as a line-transformation, because the point-image process takes place with respect to the mid-point of the boundary line of the compartment. There is another transformation which may be termed a point-transformation, because the point image process takes place with respect to an angular point of the base. In this case, the division of the base is not by lines radiating from the centre to the angular points, but by lines drawn from the centre perpendicular to the sides. The resulting transformations are co-extensive with those which have been studied, and lead to a corresponding symmetrical calculus. They are chiefly of theoretical interest, and have been developed elsewhere. Since they lead invariably to archipelago repeats, or, at most, to those of a peninsular nature, they would not be of great interest to those engaged in practical applications. An exception must be made to this statement in the case of certain combinations of point and line transformations, but this feature cannot be taken up on the present occasion. Speaking generally we are not bound down to the particular division of the triangle (or other base) that has been employed to determine compartments. Any division of the triangle into three parts can be taken as determining the regions within which the transformation patterns may be drawn.

While shewing upon the screen a selection of designs of repeating patterns that result from the principles that have been set forth, I draw attention to some special points of interest.

COMPLEMENTARY REPEATING PATTERNS.

It is possible, in general, to draw a contour surrounding any pattern, which has the property that the area inside the contour which is not part of the area of the pattern is itself a repeating pattern. The two

patterns may be termed "complementary" in regard to the external contour.

In general, this external contour can be drawn in an unlimited number of ways.

Under certain conditions which can be specified, the external contour has the property that the whole area which it includes is a repeating pattern.

Thus, when the base is an equilateral triangle, we take O for the centre of the triangle, join it to the vertices and reflect the compartments OBC , OCA , OAB , in the sides, BC , CA , AB respectively producing the external regular hexagon. We can now draw the transformation patterns within the figure OD , OE , OF , each of which is a rhombus.

FIG. 12

Taking in particular the rhombus OE the pattern, for the first nature of contact, consists of any system of closed contours within the triangle ACE and then a system, point images of these with respect to the mid-point of AC , within the triangle AOC . We note that the triangle AOC is the point-image of AEC , so that those areas of triangles AEC , AOC , which are not included within the said closed contours, must also be in point-image relation and therefore give a complementary transformation pattern. If we take these complementary transformations in the case of each compartment of the base, we are led to a complementary repeating pattern.

The two repeats are complementary with respect to the external hexagon, and since the latter is determined by a particular division of the base into three parts, we are equally justified in saying that they are complementary in respect of a dissection of the base triangle into three parts. The fact is that any dissection of the base may be taken to determine transformation areas, an external contour and pairs of repeating patterns. Similar considerations apply when the transformation appertains to the second nature of contact, and it is thence established that the principle of complementary repeats is of universal application.

EVERY QUADRILATERAL FIGURE IS A REPEATING PATTERN.

This important fact came to light at an early stage of the investigation. A search in mathematical literature revealed that this was known for figures restricted to be convex, but that, apparently, it had not been realised that it was also true when the figure possesses a re-entering angle. The proof is very simple, and may be made to depend upon the circumstance that the sum of the interior angles is equal to four right angles. It may appear, ultimately, that the complete theorem has been previously stated, but there is no doubt whatever that it has not been realised in circles likely to be well informed. A parquet floor can be constructed with four sided blocks of any shape, and a curious result follows. If it were the intention to use rectangular blocks, and by a mistake in setting the circular saw (or otherwise), each block were slightly different (but by the same amount) from the rectangular found, it would not be necessary to scrap them all; the floor can still be laid without any difficulty.

In assemblage the four-sided figure always presents two aspects. If two such figures, the four sides being of unequal lengths, be assembled, two sides of equal lengths must be in contact and the resulting figure is a hexagon which has each pair of opposite sides equal and parallel. This hexagon is a well known repeating pattern. However, it has been recently shown that it is only *necessary* for a hexagon to have one pair of opposite sides equal and parallel for it to possess the repeating property.

AN EQUILATERAL PENTAGON REPEATING PATTERN.

A regular pentagon, which has equal angles as well as equal sides, is not a repeating pattern. There is a certain degree of misconception in this matter, arising from the circumstance that a regular pentagon frequently appears in repeating pattern designs. In such cases, it is invariably accompanied by some other figure or figures so that the combination is a repeating pattern. It will be shewn later that a figure which does not repeat, can always be added to so as to convert it into one which possesses the desired property.

There are several equilateral pentagons of the required nature, but there is one which

is more nearly regular than the others, and which can be constructed in the following manner :—

FIG. 13.

From the middle point O of AB draw OC, OE, making angles of 45° with AB. Make BC and AE equal to AB and the angles BCD, AED right angles. ABCDE is the repeating pentagon which can be derived by transformation from a square base. A tessellation of these is shewn, whence it appears that the assemblage exhibits four aspects, and that it can be derived from two similar systems of hexagons at right angles to one another. The intersections of the systems shew each hexagon of both systems to be composed of four of the pentagons of different aspects.

This pentagon can be used as a base for transformation. An example of a repeat derived from it and the assemblage, is thrown upon the screen.

If a particular repeat gives a satisfactory result when it is assembled, a repeat complementary to it may be assembled with a fair prospect of success. The assemblage complementary to the one shewn in respect of one of the simplest external contours that can be drawn, is of the same general character and quite interesting. The point has not, however, been tested to any great extent.

The transformation of the square base presents some novel features. When the compartments are determined by the diagonals it yields no fewer than 27 types of repeats, each of which includes an infinite number of examples. The assemblage must exhibit either one, two or four aspects and one category, specimens of which have been shown, can be assembled so as to exhibit either one, two or four aspects. The property of a repeat in regard to aspects is an important help in the classification. It will have been observed, in the case of the equilateral triangle base when the compartments are determined by lines joining the centre to the angular points, that the reflexion of the compartments in the sides produces an external boundary which is a regular hexagon. When the base is a square the same geometrical construction produces

an external square of twice the area of the base and differing in orientation by 45° . This circumstance that the square figure again appears leads to interesting results. If any repeating pattern be constructed upon the square base, the transformation pattern being restricted to lie within the area formed by the compartment and its reflexion there exists a *repeating geometrical process*, which results, each time it is carried out, in a square of double the area, within which are two complementary repeating patterns. These can be evolved any number of times at pleasure, and the process always leaves the original repeat as the central feature. The process is, in fact, effective in producing at once an expansion and a centralization of the repeat. To obtain the most interesting patterns the chosen repeat should have quadrangular symmetry. Any design, possessing for choice the symmetry mentioned, may be chosen, although it is not a repeat, and the results of the

first application of the process is to convert it into a repeat and then the construction may proceed as before. A number of these centralizations are shown upon the screen (Plate 1). They are possibly the most complicated repeating patterns that have ever been constructed. Notwithstanding this they are interesting and deserving of close examination.

The rectangle and the parallelogram can be similarly but less effectively treated.

It will be noted that here the design is dependent essentially upon a repeating process and not upon the assembling of a repeating pattern.

From the above we are naturally led to consider the general question of converting a pattern which does not repeat into a repeating pattern. Examples have already been given in the case of the Maltese Cross, the Victoria Cross and the Grand Cross of the Bath and of some other patterns.

PLATE I.
Centralized Repeating Patterns.

Of the crosses commonly met with, the Greek Cross, composed of five squares and the Latin Cross composed of six squares are already repeats. In the case of other equal and unequal armed crosses, we may proceed in more than one way in order to effect the conversion. We may circumscribe a square or rectangle and making use of the principle of transformation convert the cross into a stencil repeat of which it is the central feature or we use the same principle to make some small alteration in the shape which will cause it to possess the repeating property. Some examples are illustrated.

FIG. 14.

FIG. 15.

When a wall or other flat surface is decorated by means of floral or other designs equally spaced, it may not be immediately evident that we are in the presence of a repeating pattern, as it has been defined at the commencement of the paper. That this is so, as regards the external contour of the design, is shown by the accompanying diagram (Fig. 16). The design is shown, diagrammatically, placed at the centre of each cell of a square tessellation. The repeating pattern is then seen to be the archipelago and stencil combination denoted by the shaded areas. All such decorations can,

therefore, be duly entered in their proper places in the classification.

FIG. 16.

The question of aspects assumes increased importance when we come to the study of the transformations on the regular hexagonal base. In this case there are three general systems of contact and one of these has the property that all the derived repeats, infinite in number, are exhibited in three aspects when assembled. This is remarkable because a diligent search has not resulted in discovering, in ancient or modern work, any assemblage with this number of aspects. The reason why three aspects present themselves is that three is a divisor of six, while the hexagon itself can be assembled so as to show only one aspect. The number three does not appear when the regular triangle is the base, because, since the triangle itself shows when assembled two aspects, the derived repeats must show a number of aspects which is a multiple of two. It does not appear when the base is any quadrilateral, because three is not a divisor of four.

Examples of these repeats and an assemblage are shown upon the screen (Plate II.)

Some hundreds of categories of repeats are derived from the regular and some special hexagons by the transformations. A few of these are exhibited (Plates III., IV.)

In conclusion, it may be stated that there are many other principles available for the study of this subject.

There is the principle of dissection arising from the circumstance that if any repeat can be dissected into a number of identical figures, such figure is necessarily a repeat.

The principle of "composition" which appears because in an assemblage of repeats it is possible to draw around a certain number a boundary which encloses a repeat composed of a number of identical repeats.

PLATE III.

Repeating Patterns designed from triangular and quadrangular bases.

12

PLATE II.

Some Assemblages of Repeating Patterns.

PLATE IV.

Repeating Patterns derived from hexagonal and pentagonal bases.

The principle of "absorption" which presents itself because, in an assemblage, certain selected figures can be made to absorb portions of neighbouring figures and so fill up the space as required.

The principle of "translation," which was enunciated by Lord Kelvin in connection with the homogenous partitioning of space of three dimensions.

The principle of "continuous growth" of equal and similar and similarly oriented contours placed at points which are uniformly distributed.

The principle of taking large ruled and cross-ruled areas covered with long lines straight or waved (to use the vernacular of some of the art text books) according to definite laws, when the spaces between such lines are seen to be repeating patterns.

All of these methods were examined, but they were found to be inferior for the

purposes of design and classification and thorough exploration of the field, to the principle of transformation adopted in this research. This principle appears to be new to the subject. In its general uses the other principles should be constantly borne in mind and will be found to be useful auxiliaries.

The connection of the principle of transformation with the last-named principle of long straight or waved lines may suitably be the subject of some observations. When any repeating pattern is assembled so as to cover a definite area it is always possible to draw through it systems of long lines, straight or waved, which are seen by their intersections to produce the patterns.

Conversely we may design, in a variety of ways, these systems of long lines and thus produce the patterns, which, of course, cannot be either of the stencil or architectural types.

It follows that this principle, if carried out to the fullest extent, can only deal with about 20 per cent. of the ground to be explored. Now the principle of transformation deals with assemblages of the simplest repeating patterns and the transformations of the compartment boundaries effectively transform all the long lines that can be observed passing through the assemblage. It transforms them in every possible manner into other long lines passing through assemblages of other repeats; but not only so, it also so transforms them that they cease to be long lines straight or wavy, and the repeats that existed initially are turned into stencil or archipelago repeats or combinations of these. It follows that the principle not only does, what the long line principle can do, in a far more thorough manner, but it also deals with the remaining 80 per cent. of the ground that that principle, as it exists to-day, cannot touch. Repeating patterns have been recently sent to me from China, Japan, Peru, India, Egypt and many other parts of the world, but I have never failed to place any specimen in its proper place in the classification that had been previously constructed. This encourages me to hope that the classification suffices for all practical purposes.

I may add that at least 90 per cent. of the few hundreds of categories have apparently never been drawn upon for practical application.

DISCUSSION.

THE CHAIRMAN said that he was sure the paper had kept the attention of members of the audience fully on the stretch, and if they had followed every convolution as Major MacMahon had developed it, they had undergone a very strenuous intellectual exercise. He confessed that here and there he would like to read passages in the paper over again at leisure and consider them with more time at his disposal. But what had struck him, amongst other things, was the number of ancient and early decorators of all ages and periods who had felt their way towards, at all events, the simpler forms of this repeating pattern. His impression was that there was a repeating pattern of the curvilinear sort on an ancient Minoan pot discovered by Sir Arthur Evans, in Crete. All architectural design constantly employed simple forms of these repeating patterns. How far it would be wise from the aesthetic point of view to carry the elaboration of such patterns he would not attempt at the moment to suggest. It was conceivable that too great an elaboration might defeat the object of the repetition which

aesthetically had the purpose rather of being restful than agitative. Some of the designs which Major MacMahon had elaborated certainly seemed to him to possess artistic possibilities. Did he understand him correctly to say that there was no real instance of repeating patterns produced from circles?

MAJOR MACMAHON stated that he had not found any.

THE CHAIRMAN: Yet we had surfaces entirely filled with those intersecting circles repeating over and over again.

(The Chairman here demonstrated on the blackboard the kind of form he had in mind in suggesting that repeating patterns might be produced from circles). He added that this pattern was common in late Roman times and in early Coptic art. It came over to the west along with early Gothic goldsmithry in the fourth and fifth centuries, and appeared in England in the seventh century, and was, he supposed, the commonest repeating pattern in barbarian Anglo-Saxon art.

SIR FRANCIS PIGGOTT, whose remarks were illustrated by a number of lantern slides, said he rejoiced that so eminent a mathematician as Major MacMahon should have turned from the austerities of his favourite subject and found recreation in decorative design; because he had always believed that there were mysterious links at present undiscovered between science and art. But he was diffident of talking on the subject, because his scientific knowledge was of the scantiest, and he begged indulgence for any slips he might make. He would not like what he was going to say to be regarded as criticism of the very learned paper they had listened to; he would rather put it forward as a view which had gradually been shaping itself in his mind during a long period of study of decorative design. It was a view which differed almost at all points from that elaborated by Major MacMahon, though it would not be the first time that the same result had been reached by different paths. First: his cardinal principle was that design, like everything else, was subject to a law of natural evolution, and that the most complicated designs could be traced back to some early form. It was not always easy to discover the intermediate stages of development; but in two cases, as he showed in a paper read before the Society in July, 1919, he had actually discovered examples of practically all the progressive stages of development of two very different schemes of design in the Japanese temples. These were (a) the elaborate diaper known familiarly as the "Cloisonné pattern," and (b) the equally elaborate traceries of the lattices. Secondly: believing as he did in natural evolution, it followed that he rebelled at the idea of "assembling" a series of repeated

designs. The two ideas were antagonistic. "Assembling" implied starting with the design, and working backwards instead of forwards. And it had this peril, that if the principle on which the design was based was not accurately appreciated, the repeats would not work properly; the completed tessellation would be full of flaws. As an example and a warning, he might refer to what was commonly called the "Greek Key Pattern." The Greeks borrowed it from the East, but knowing nothing of its evolution from the Cloisonné diaper, produced some variants which were merely artistic monstrosities, formless and void. The "Key" border or fret was a section cut transversely to the structure of the diaper; and he noted here that this diaper was the only case he could call to mind of an Eastern design which was "assembled," its component parts being limbs of the Pakwa symbol. Thirdly: He did not accept the equilateral triangle as a true repeating unit, because it involved the introduction of the "inverted repeat" out of due time. Inversion of the unit of design came later in the stages of evolution. He thought the rhombus, of which the triangle was the half, was the true repeat.

These things said, he would now endeavour to explain what he thought was the gradual evolution of repeated design. One class of natural forms was the result of forces constant in their action. By "form" he meant a space enclosed by one or more lines; which was sufficiently accurate for the purpose in hand, though it would exclude the catenary, the spiral, and the whorl, which were properly described as "forms," and which were natural forms. If we took a point from which force was constantly radiating in all directions, and it was cut by a line equidistant in its entire length from the point of force, we got in two dimensions the circle; if it was cut by a curved plane we got, in three dimensions, the sphere. He thought this was the first natural form; and it had, possibly from this cause, always had a sacred or mystic significance in the East. The most beautiful designs were contained in a circle, the detail radiating tangentially and internally from the circumference. The division of the circle into two equal parts by opposed tangential semi-circles on the two halves of the diameter was the Eastern symbol of completeness, the Yang and the Ying, the symbolic representation of the positive and the negative, the one complementary to the other. Again, if we took a series of points of force, all of them equidistant from one another (arranged, that is, on the points of a series of equilateral triangles) then the forces, radiating as before constantly and equally in all directions, when they met, would annihilate one another, and the various lines of meeting form a series or "repeat" of hexagons; and he thought this was the second

natural form: The bees, packed closely to one another in their hive, were points of force, and they formed the honeycomb, which was the natural demonstration of this law. The hexagon too, was the law of the snow crystal. He imagined that if the expansion were in three dimensions there would result a sphere with flattened hexagonal surfaces. It was interesting to note that the Lattice Fungus was a sphere with flattened pentagonal shapes, more or less regular. The conic sections and the cardioid were also natural forms, but they were independent of forces in their construction. Now human agency came into play, and we found man assisting in the evolution of form, though not at first deliberately. He filled in the light and air cavities in the walls of his house with laths, from which repeated forms resulted—the square, the rectangle, and the lozenge. Here we had forms repeated which after having served for use became groundworks of ornamentation: which sometimes depended merely on the simple forms repeated, or they were filled with designs shaped to the forms which were themselves repeated simply or with variations.

The intersecting lath had been a very important factor in the evolution of repeated design, for the large family of lattices depended on it; and this brought him to the last of his differences with the author. He said, and truly, that "When any repeating pattern is assembled so as to cover a definite area, it is always possible to draw through it systems of long lines straight or waved, which are seen by their intersections to produce the patterns. Conversely, we may design, in a variety of ways, these systems of long lines and thus produce the patterns." But having lived among them for many years, and having imbibed the spirit of the workers and their work, he (the speaker) could come to no other conclusion than that the "long line," or the lath, was the fount and origin of repeated rectangular design. Some of the lattices were painfully intricate, and he doubted, with the utmost deference, whether it would be possible to design the resulting forms without the lath, much less assemble them.

The speaker then showed what he described as the most complicated lattice he knew, and it depended entirely on the series of intersecting laths, with a kink in the middle, which had given it its name the "Lightning Lattice." The laths themselves gave an interesting pattern and the light space was also a repeating figure which was well-known in Japanese heraldry. As he had said once before, if an architect wanted to devise a punishment for a refractory pupil, he should set him to work to draw it. And he would conclude his remarks with this question to Major MacMahon: Given these repeating figures, could he really assemble them? He noted that Major MacMahon defined a "repeat" as one which, when the identical

figures were assembled, filled a given space of two dimensions "without leaving any interstices"; but the special feature of Japanese repeated design was that there were interstices, and that these were themselves the elements of a repeated design, which sometimes was the primary, and sometimes the secondary, characteristic of the whole composition.

SIR HERCULES READ, LL.D., F.B.A., said that he was not at all prepared to enter the arena on the strictly scientific side that, very naturally, Major MacMahon had taken up. His experience in patterns of this sort was entirely from the empirical side, and in that respect he would much have preferred to cross swords for a moment with the last speaker, whose remarks showed him to have been convinced by certain widely spread heresies. However, it would not be fair to discuss a discussion, and so he would say a few words in relation to the paper itself. He had talked with Major MacMahon a year or more ago on this subject, and had shown him then a certain number of handsomely illustrated books containing a great variety of repeated designs, which he (Major MacMahon) looked at with very considerable interest. The greater number of these were of Moorish construction. Major MacMahon had said nothing at all, perhaps wisely and cautiously, about whether or no the Moors who constructed these superficial designs for their buildings worked by rule of thumb, or had behind them some such principle as he had laid before the Society that evening. He thought that was rather an interesting side to the investigation, because, as he was sure nobody knew better than Major MacMahon himself, there were no greater mathematicians in the early Middle Ages than the Moors and the Arabs, to whom were owing those very charming designs seen in the Alhambra and other great buildings erected in Spain and elsewhere. They were obliged to use this particular form of decoration, because their very rigid creed forbade them to use living forms; therefore, they adopted the conventions which Major MacMahon had shown so well that evening for decorating the walls of their buildings. But these Moorish designs were so various, and, he thought, almost invariably so beautiful, as well as so unusually accurate, that it seemed to him almost inconceivable that there should not have been behind them some such principle as Major MacMahon had laid down. Whether there was any evidence for or against it, he was quite unaware; but when one had a nation of mathematicians building with patterns of this sort, there was a *prima facie* case for believing that they pursued their construction on given principles. One other point he might mention—and here he thought Major MacMahon did make a definite statement—concerning the Chinese. The author had suggested that

because the Chinese only used one particular form of interlocking arrangement, therefore they were not possessed of any knowledge of principle, otherwise they would have used more. That, he thought, supposed a greater love of variety in ornamental forms than was found among the Chinese. The speaker was fairly familiar with Chinese works of art, from the very earliest times up to their products of the day before yesterday, and the one thing to be discovered was uniformity and monotony of design, where a greater variety would have been infinitely more pleasing, at any rate to our eyes. His argument was that, because one only found this one special form of ornamental repeating design, it was not a safe deduction to suppose that the Chinese were not aware of any underlying principle. There, again, one had to deal with a race of the highest intellect, and it seemed to him not unlikely from his knowledge of them and their ways, that they also were likely to have been possessed of the principle underlying all this repeating pattern business.

Sir Francis Piggott had alluded to the greater charm that in his eyes—and in the speaker's also, for that matter—came from what might be called the evolution of the natural process from one design to another, and had said that the designs produced by such evolutionary methods were more agreeable than those which Major MacMahon had put on the screen, and which were founded on a strictly scientific principle carried out with the greatest possible care. In that respect, it seemed to him (the speaker), that they could hardly be agreed or judicial on such a point. The matter was as yet in its infancy, and here, again, he was sure that the lecturer would agree with him that there were infinite possibilities in patterns which might be more pleasing to the artistic eye than those which, in the elementary stages of carrying out his principle, he had shown as illustrations that evening. There was a certain aridity about the design of the latter, a want of artistic freedom, a lack of charm in line and contour, which was probably not due to the method whereby they were produced, but only to the fact that the method was quite novel to them. He must compliment Major MacMahon upon having given the Society, without question, one of the most ingenious solutions of many of these problems of which he had ever heard. The speaker had been intensely interested from beginning to end.

DR. E. H. HANKIN said with regard to the suggestion that Moorish artists employed methods of design similar to that now developed with so much ingenuity by Major MacMahon, a reference might be made to a paper that he had read before the Society in 1905 that dealt with some discoveries of methods of design

in Saracenic art.* A further and more detailed description of these patterns was about to be published in the *Memoirs of the Archaeological Department of the Government of India*. Nothing would be found in this description that recalled in any way the discoveries of Major MacMahon. A reason why his work was welcome was that there was a constant need for the discovery of new geometrical patterns. These patterns rapidly became monotonous by repetition. The standard aimed at, and generally achieved, in Saracenic art was that no two panels or decorated spaces in a building should have the same pattern. This urgent need for novelty inevitably led to complexity. At length at the highest development of this art, its patterns showed monotony in their complexity. Their complexity was far beyond what the ordinary onlooker could appreciate. As the proverb said, there was no accounting for tastes. Whether a particular pattern was pleasing or not depended on qualities that for the most part could not be estimated or valued by conscious reason. We had had examples of this fact to-night. Nearly all of the simpler patterns shown by Major MacMahon, however they might have appealed to us intellectually, had no kind of æsthetic value. It was only the more complicated of his patterns shown at the end of the lecture that were pleasing to our artistic sense. Their greater complexity could only be a part reason for the difference, for in Saracenic art we often found patterns of great simplicity but yet of comparatively high æsthetic value. A feature in which Major MacMahon's patterns seemed to be inferior to those of Saracenic art was that in the latter the different pattern outlines were usually interdependent. A line that limited one side of a pattern space on being followed was found, for instance, to be part of an octagon, while the line limiting the other side of the same space was part of another octagon. Or, in the more complicated of these patterns, every line was seen to run a zig-zag course right through the pattern from one side to the other. No line came to a dead end. Each line after bounding one pattern space was continued to assist in bounding other pattern spaces. Generally, if necessary, the lines could be drawn interlaced, passing alternately over and under all the other lines of the pattern that they met. With Major MacMahon's patterns, on the contrary, there were numerous dead ends. Each line enclosed its own pattern space and took no part in forming boundaries of neighbouring spaces, except of course in so far as one space was contiguous with its neighbours. Owing to this character these patterns seemed more fitted for mosaic pavements, for instance, which were made up of separate pieces than for decoration of panels, dados or friezes where a continued pattern

seemed more appropriate. These considerations indicated the direction in which some practical use might be found for Major MacMahon's very ingenious and striking researches.

THE CHAIRMAN said that the Society would desire to return its hearty thanks to Major MacMahon for his delightful and ingenious address. What he had told them had been obviously the result of an enormous amount of work, and the Society must reckon itself fortunate to have heard from him the results at which he had arrived.

The vote of thanks was accorded unanimously.

MAJOR MACMAHON, after thanking the Chairman and the Society, replied to some of the points raised in the discussion. With reference to what the Chairman had said about the circular pattern which he had drawn on the blackboard, that was not properly a repeating pattern until certain other lines were drawn. When these other lines were drawn, a repeating pattern was disentangled from it, but until that was done, there was nothing in the design which answered the definition of a repeating pattern—namely, a particular shape which, when repeated, could be made to fill all space. That, of course, was a feature of a great many designs, interlacings of lines, and many Arabesque designs. Those were not "repeats" in the sense in which he had used the word scientifically that evening. But from such designs repeats could be extracted, sometimes on making further dissections by adding certain lines; from many of the designs shown by Sir Francis Piggott on the screen one could without modification make repeats of a particular area. That was the sense in which he had used the word "repeat."

All Sir Francis Piggott's designs were extremely instructive, and repeats could be derived with very little difficulty from them. Sir Francis had spoken about evolution. In the paper that evening, however, he had himself referred in his concluding remarks to the principle of continuous growth of equal and similar and similarly oriented contours placed at points which were uniformly distributed. That was a well-known principle in discussing this matter of repeating patterns which was particularly brought forward by Lord Kelvin in regard to three dimensions in his researches on atomic structure, and which was now being considered and written about by Sir Joseph Thomson, in the same regard. Of course, that was a very interesting principle, but it was not a principle which lent itself to a classification of repeating patterns. What he himself had had in view had been a definite classification, and neither the principle of continuous growth nor the other principles mentioned lent themselves to this purpose. One had to go to the ultimate forms

* "On some discoveries of methods of design employed in Mahomedan art"—this *Journal*, Vol. LIII., March 17, 1905, p. 461.

of things if one was to arrive at a scientific principle of classification, and that was what he had had in mind. Sir Francis Piggott had referred to the cells of bees. Perhaps he was not aware that that subject had been gone into very thoroughly by Cambridge mathematicians, particularly by Dr. Glaisher, of Trinity College, who in a lecture many years ago, referring to bees, had given his opinion without hesitation that the bees were not in it with mathematicians! The mathematicians could make these cells far better than the bees, and as Dr. Glaisher had gone into the matter he (the speaker) naturally assumed that he knew what he was talking about. With regard to this question of continuous growth, Sir Francis Piggott had spoken of spheres with hexagonal surfaces.

SIR FRANCIS PIGGOTT said his scientific terminology might have been wrong. There was a spherical fungus—the lattice moss—which had flat surfaces in pentagonal shapes, and he suggested that there might be a hexagonal shape.

MAJOR MACMAHON said that the shape that naturally arose in three dimensions on the principle of evolution was not hexagonal or pentagonal with regard to its surface. It was a solid known as the rhombic dodecahedron which, as it faces, had twelve rhombs. He was very much interested to hear what had been said about Japanese heraldry, but to many designs of the Japanese the same remark applied; they were not repeats, though they could easily be made such. He thought that Sir Hercules Read was quite right in what he had said about the Chinese. He had no doubt that the Chinese mathematicians had gone deeply into this matter, but he wondered sometimes why in Chinese work one saw nowhere any recognition of the stencil repeats. The Moors also, no doubt, knew a great deal more which they did not publish. He had had an interesting letter recently from Dr. Hankin, who had been studying the Moorish designs. These were not directly repeating patterns, at least in a great many cases, but repeating patterns were very easily extracted from them, and he thought that Dr. Hankin had made a great advance in discovering the way in which these Moorish designers went to work. He was to be congratulated on elucidating the methods which they employed.

CORRESPONDENCE.

OIL BEARING NUTS IN GUATEMALA.

Referring to the article under this caption in the *Journal* of June 16th, I would point out that large quantities of Cohune Nuts are annually rotting in British Honduras, merely for the want of a suitable machine to crack the nuts,

without breaking the kernels. If the machine referred to is really suitable and can be worked by unskilled labour, it would be a great boon to the Colony to have it introduced there, by bringing it to the notice of the Chamber of Commerce at Belize. The little Colony wants all its resources developed to get it into a flourishing condition, and if these lines were to contribute somewhat to that end, I should be extremely pleased.

H. E. OSWALD.

NOTES ON BOOKS.

THE WORK AND POSITION OF THE METALLURGICAL CHEMIST. By Sir Robert A. Hadfield. London: Obtainable from Messrs. Charles Griffin and Co., Ltd. Sheffield: From Mr. W. H. Seed. 1921.

A well-illustrated volume of a hundred pages, which embodies the matter of the author's address to an assembly of metallurgists at Sheffield.

Sheffield, Lord Palmerston's "Black picture set in a golden frame," and a modern embodiment of the sentiment by which Greek mythology makes Vulcan the husband of Venus, is to Sir Robert Hadfield the high place of the world, and it is evident that he sees everything relating to Sheffield or the steel industry as in a poetic halo. As a man of Sheffield, Sir Robert looks back proudly (p. 13) on the fact that Chaucer recognised the merits of Sheffield products, and on the same page he drifts over to a kindred district in France, Le Creusot and its great forge, where he and his fellow members of the Iron and Steel Institute were so graciously received by Madame Schneider, who is a direct descendant of James II. and Arabella Churchill.

Intense admiration for all honest and faithful labourers is the dominant key-note of the book: the print from the bust of Robert Boyle (frontispiece) being an illustration of this. Boyle is styled the "Father of modern chemistry," and Sir Robert, on a folder opposite p. 22, classifies chemists, with that ready insight which may be expected from an old laboratory worker. The premier position which is claimed for Boyle seems justified when we remember that apart from his definite experimental work, he was the first to present chemistry as an ordered system with clear notions regarding element, compound, mixture, analysis, synthesis and molecular constitution.

Detail and technics in the work before us centre to a considerable extent on the work of the metallurgical chemist in evolving and adjusting qualities of steel as used in the Great War, and as an example of unexpected difficulties which were overcome, reference is made to the adaptation of manganese steel to the construction of the helmets or "tin hats," which became so important towards the close of the war, the difficulty being to reduce the large-

sized ingots of this resistant material to the necessary thickness, or about one-thirtieth of an inch.

Plate 19 shows French, British and German helmets under test conditions, with clear indications as to the superiority of those made of manganese steel, which in this application is the culmination of the work of a long series of British investigators.

Numerous illustrations, many of them portraits, add to the interest of the book.

THE AGRICULTURAL AND FOREST PRODUCTS OF BRITISH WEST AFRICA. By Gerald C. Dudgeon. Second edition. London: John Murray. 1922. 7s. 6d. net.

Here we have a new edition of a volume in the well-known series issued under the auspices of the Imperial Institute, in which series in industrial geography is so usefully and thoroughly studied, and in special reference to the resources of the British Empire.

The large range of products, mainly vegetable, but occasionally animal, here considered, and the many details as to collection, storage or factorage, together with the abundant particulars as to more or less elaborate industrial processes, give the book a somewhat discursive aspect, and the discursive aspect will perhaps tend to make the volume one which the business man or manufacturer can take up with advantage and comfort in leisure moments; in deed, the text (nearly 200 pages) and the numerous maps and inset plates, make the whole a rapidly changing panorama of life and activity in districts where till recent medical studies had borne fruit the white races could only settle at considerable risk. The admirable index of twelve pages links all together, and the item "Silver" in the index led us to p. 55, where we find that, in the Volta cocoa-buying centre, buyers must be provided with silver, notes and cheques not being accepted. Here is an example of the many hints or particulars as to business matters. On the same page is an explanation as to how the native of this district will be contented with less when working for himself than when working for an employer, while on pages 24 and 25 will be found a short account of the three principal considerations which are believed to have influenced Messrs. Lever Brothers in abandoning their oil-products establishment in Sierra Leone, also their concession to work several hundred square miles, Messrs. Lever Brothers having now transferred their works to the Belgian Congo.

Among the photographic illustrations, over 100 in number, the following may be specially mentioned as illustrating industries which are described in the text:—Jolah with hand plough, Indigo Dyers, Out-door Weaver at Pendembu, Straining Oil from the Fibrous Pulp of the Oil Palm, and The Ginney of the British Cotton Growing Association.

SYNTHETIC TANNINS: THEIR SYNTHESIS, INDUSTRIAL PRODUCTION AND APPLICATION. By Georg Grasser. Translated by F. G. A. Enna. London: Crosby, Lockwood and Son. 1922. 12s. net.

True or indubitable tannins are briefly considered, and such syntheses as those of Fischer are touched on p. 25, but we find no reference to any industrial uses of true synthetic tannins; a matter of doubtful practicability owing to the high cost of synthetic tannins. Thus, it may be suggested that the title of the book is not quite appropriate to the contents.

The drift away from true tannins on page 35, and throughout the remainder of the book is very noticeable, as we now find somewhat vague generalisations regarding artificial products which harden or insolubilise pelts, as, for example, aromatic sulphonic conjugates condensed or polymerised with formaldehyde and brought into alkaline solution; these appearing to us in no sense tanning materials, but as rather analogous in their function to tawing agents. It is to be noticed that on page 91 the tone of the book again changes, and we have a eulogium of the modes of manufacture carried out by the "B.A.S.F.," and of this firm's products, which are marketed under trade names; this note of eulogy continues more or less, to the end of the book, but there is one pronounced discord, in the shape of footnote 2 on p. 118 commencing "The translator cannot agree with the author——"

The author's preface should be read with care, especially the patriotic sentiments as to the course suggested making us "—— independent of foreign supplies——"; also as to keeping "within our own borders the vast sums of money required in former days for the purchase of foreign tanning material." Next let the reader note that this preface is dated from Graz, an old centre of the tanning industry in Austria; also that the initials B.A.S.F. stand for the Badische Anilin und Soda Fabrik, one of the huge German chemical establishments with which the author was associated.

We know that aryl-sulphonic condensations with formaldehyde, of the kind favoured by our author, will give a white or whitish product, somewhat resembling a tawed skin, and if such products are termed synthetic tannins, ordinary alum should, we suggest, be similarly classed.

Notwithstanding the emergency service done to both sides in the late war by the use of condensation products of the kind referred to in Herr Grasser's book, and also very concisely and well described by Mr. Henry R. Procter on p. 781, of this *Journal* dated November 8th, 1918, we suggest that further experience is desirable as regards the lastingness of "leather," "tanned" with such products, before we use them in peace times. If we should find it desirable thus to supplement our supplies of natural tannins we can manufacture the new products for ourselves.

APPLIED CALCULUS: AN INTRODUCTORY TEXT-BOOK. By F. F. P. Bisacre. London: Blackie and Son, Limited. 1921. 10s. 6d. net.

The key-note of this work, addressed primarily to the student of natural or applied science, is the sentiment of human interest in mathematics; an aspect which is so often lost to the student by reason of the habit which so many teachers have of enforcing a detailed study of much complex mechanism with signs and symbols, before the real or spiritual aspect of the subject is presented or even suggested to the learner.

Our author very pronouncedly avoids so sterilising a course, so he leaves over the study of infinite series, for a second step, and he illustrates the use of limits, by an apt reference to a scene of Shakespeare's plays (p. 28), before he attempts the somewhat difficult task of satisfactorily defining the term limit in its shades of theoretical and practical meaning (pp. 83 to 94.).

The author's birth scene of the calculus is laid in 1612, when there was an abundant vintage in Germany, with the consequent shortage of casks and the natural desire to know the contents of any unusual cask which had been filled in the haste of saving the vintage. Kepler, whose astronomical studies had led him to a determination of the areas of closed curves, gave his mind to the new problem, and published his *Nova Stereometra Doliorum*, or, as our author puts it, "The earliest work on the subject, now called the integral calculus." Next follows an explanation of the essentials of Kepler's method so clearly expressed as to be almost a lure calculated to lead the general reader into a new path of study.

In like easy and lucid fashion, the fundamental methods of the calculus are presented, in such order as to maintain interest and a natural sequence of ideas; this occupying about one-third of the book. The remainder, that is to say, the bulk of the volume, is mainly concerned with definite applications of the calculus to actual laboratory problems, about 170 in number; the following being examples of the problems:—Efficiency of ideal Diesel cycle; the Otto cycle and the nearest ideal cycle; Faraday's law of electro-magnetic induction; a reversible chemical reaction, and example of Isothermal Expansion.

Portraits and short biographical notices form a pleasant feature of Mr. Bisacre's book, Newton, the incomparable, holding the place of honour opposite the title page, the remaining 16 portraits being in four groups of four, each group on an inset plate.

LOGWOOD INDUSTRY IN JAMAICA.

Logwood was first introduced into Jamaica from Honduras, in 1715, and was later carried

to other parts of the West Indies. It will grow well on all soils, except loose sand and heavy clay, but it grows best and produces a finer heartwood on moist, rich soil where there is an abundance of vegetable matter. The climate must be hot, but not arid, although it has been found that when the plant becomes firmly rooted it stands a drought very well. Very little attempt is made to cultivate it, and most of the wood is cut from self-sown trees, which are usually found on waste lands unsuitable for cultivation.

Until quite recently, writes the United States Vice-Consul at Kingston, the production of logwood crystals has been very remunerative. A large dyeworks plant in Jamaica has been paying only £40 for sufficient raw material to make one ton of crystals, which sold in London for £200. An association of logwood growers has been formed, however, for the purpose of obtaining higher prices for their logwood. Pending the formation of this Association, the demand for both logwood and crystals declined to such an extent that the local factories were forced to close down.

There are three plants producing logwood extract in Jamaica, one in Spanish Town, one in Lacovia, and one in Savanna-la-Mar. The plant at Spanish Town is the largest. Its minimum crushing capacity is 20,000 tons (of 2,240 lb.) per year, while the plant at Lacovia has a capacity of 12,000 tons per year. Figures are not obtainable for the plant at Savanna-la-Mar, as it was completely destroyed by fire shortly after its completion. It requires from 8 to 9 tons of logwood to produce 1 ton of crystals, and a somewhat less amount to produce 1 ton of liquid extract. Crystals are always shipped in casks containing 320 pounds, while the liquid is shipped in barrels containing 650 pounds.

The following table gives the exports of logwood and extract to the United States and the United Kingdom for the years 1918 and 1919:—

Exported to	Logwood. Tons.	Value. £
United Kingdom:		
1918	1,360	4,894
1919	3,153	16,080
United States:		
1918	14,133	50,879
1919	13,928	71,032
	Logwood Extract. Packages.	Value. £
United Kingdom:		
1918	20,459	306,890
1919	22,090	331,800
United States:		
1918	550	8,250
1919	329	4,935

Journal of the Royal Society of Arts.

No. 3.633

VOL. LXX.

FRIDAY, JULY 7, 1922.

All communications for the Society should be addressed to the Secretary John Street Adelphi, W.C. (2)

NOTICE.

PRESENTATION OF THE SOCIETY'S ALBERT MEDAL TO SIR DUGALD CLERK.

The Council of the Royal Society of Arts attended at Clarence House, St. James's, on June 29th, when His Royal Highness the Duke of Connaught and Strathearn, K.G., President of the Society, presented the Albert Medal of the Society for the present year to Sir Dugald Clerk, K.B.E., D.Sc., LL.D., F.R.S., "in recognition of his important contributions, both theoretical and practical, to the development of the Internal Combustion Engine."

The following members of the Council were present:—

Mr Alan A Campbell Swinton, F.R.S., Chairman of the Council, Lord Askwith, K.B.E., D.C.L., Sir Charles Stuart Bayley, G.C.I.E., K.C.S.I., Lord Blyth, Sir William H Clark, K.C.S.I., C.M.G., Mr Edward Dent, M.A., Sir R. A. Hadfield, Bt., D.Sc., D.Met., F.R.S., John S Highfield, M.Inst.C.E., M.I.E.E., Major Percy A. MacMahon, R.A., LL.D., Sc.D., F.R.S., Dr. William Henry Maw, M.Inst.C.E., Mr. John Slater, F.R.I.B.A., Mr. James Swinburne, F.R.S., Sir Philip Watts, K.C.B., LL.D., F.R.S., with Mr. G. K. Menzies (Secretary of the Society) and Mr. S. Digby, C.I.E. (Secretary of the Indian and Dominions and Colonies Sections).

PROCEEDINGS OF THE SOCIETY.

ANNUAL GENERAL MEETING.

The One Hundred and Sixty-eighth Annual General Meeting for receiving the Report of the Council, and the Treasurers' Statement of Receipts and Payments during the past year, and also for the Election of Officers and New Fellows, was held in accordance with the By-laws on Wednesday, June 28th, at 4 p.m., MR. ALAN A. CAMPBELL SWINTON, F.R.S., Chairman of the Council, in the Chair.

The Secretary read the notice convening the meeting, and the Minutes of the last Annual General Meeting held on June 29th, 1921.

The following candidates were proposed, balloted for, and duly elected Fellows of the Society:—

Baneroff, William Wilfrid, Ilford, Essex.

Beall, F. F. Detroit, Mich., U.S.A.

Chaudhuri, S. N., M.A., Calcutta, India.

Cook, C. F., Hove, Sussex.

Dalal, Dadiba Merwanjee, C.I.E., India Office, S.W.

Doyle, William, B.A., Loughborough

Drummond, L. E., Edmonton, Canada.

Eardley, Walter H., D.Sc., Salt Lake City, U.S.A.

Frank, John Williamson, Vancouver, B.C.

Galliver, George Alfred, M.D., Holyoke, U.S.A.

Gillam, William Thomas, Luton, Beds.

Jamieson, A. Eldon, Edmonton, Canada

Javeri, Ratilal C., Bombay, India.

Kaye, Robert Walter, Leicester.

Kilachand, T., Bombay, India.

Macartney, Rt. Hon Sir William Grey Ellison, K.C.M.G., London.

McLeish, Rev Alexander, Rajputana, India.

Mappin, Godfrey Edward, Ingatestone, Essex.

Mukherjee, Tarak Nath, Bengal, India.

Palairot, Charles R., Indore, India.

Roberts, Arthur Lawrence, Birmingham.

Small, Frank S., B.Sc., New York City, U.S.A.

Stannard, H. Sylvester, Bedford.

Sullivan, Haldane Herbert, Risca, Mon

Worden, Edward Chauncey, Ph.C., D.Sc., F.C.S., New Jersey, U.S.A.

THE CHAIRMAN appointed Mr. Byron Brenan, C.M.G., and Mr. Charles Oliver Barber, B.Sc., F.C.S., Scrutineers, and declared the ballot open.

THE CHAIRMAN said the first item of business was a very pleasant one, as it was his duty, on behalf of the Council to present a cheque for fifty pounds to Mr. George Davenport, the Chief Clerk, on his completion of 50 years' service with the Society. They all knew Mr. Davenport, and he did not think it was necessary for him to say very much about him. Mr. Davenport had been connected with the Society for fifty years, and he had contributed largely to the success of the meetings by the way in

which he had handled the lantern and by the valuable assistance he had rendered whenever preparations were required for experiments, etc. Speaking from his own experience, and also what he had heard from other lecturers, he said Mr. Davenport had been of the greatest service in making preparations for papers and lectures, and had shown great willingness to do everything he could to help them. He had very much pleasure in presenting the cheque to Mr. Davenport and wished him long life to continue in the Society's service.

MR. GEORGE DAVENPORT, thanked the Chairman for the kind words he had spoken and the Council for their generous gift. He said it hardly seemed possible so long a time had elapsed since he first came there, but he thought this was largely due to the interesting nature of the work, and to the very great pleasure it had given him to help in his own small way in carrying it out. He greatly valued this expression of appreciation of the Council, and hoped he might have opportunities in the future of still further deserving their approval.

THE SECRETARY then read the following Report of Council:—

REPORT OF COUNCIL.

I.—THE SOCIETY'S HOUSE.

In the last Annual Report it was stated that the question of the Society's House was causing the Council grave concern. The lease was terminable in March, 1922, and a sum of £50,000 was required to purchase the freehold of the property and to provide for necessary decoration and repairs. Towards this amount some £8,000 had been promised by several members of the Council and their friends, but in the generally depressed condition of the country there seemed to be but little hope of raising the remainder. At this point, however, a gentleman, who desires to remain anonymous, came forward and contributed the munificent sum of £30,000. The Council thereupon decided to issue an Appeal to the Fellows, with the result that up to the present, about £42,500 has been obtained. The Council have great pleasure in reporting that they have now secured the freehold of the premises; but in order to provide for the legal expenses and for alterations, decorations, etc., they have been compelled to arrange for a running overdraft with their bankers. They take this opportunity of again appealing to the liberality of the Fellows to assist them in paying off this overdraft.

Now that the house has become the permanent property of the Society, the Council are anxious to make it as convenient and attractive as possible for the Fellows. They desire to restore it, so far as is compatible with modern requirements, to the state in which it was left by its architects, the Brothers Adam. With this end in view they have appointed Mr. Arthur T. Bolton, F.R.I.B.A., Curator of the Soane Museum, to take charge of the renovations. It is hoped to make the library into a handsome and comfortable club room; the Great Hall will be entirely redecorated and provided with a new system of ventilation; and the entrance hall will be considerably enlarged and improved. The heating and lighting throughout the building will receive very careful attention, and every effort will be made to encourage Fellows who desire to use the Library and Reading Room.

In order to carry out this work it will probably be necessary to close the Library from the beginning of July to the end of November.

II.—ORDINARY MEETINGS.

Mr. Alan A. Campbell Swinton, in the introductory remarks of his inaugural address, summarised the position of the Society with regard to the purchase of its house, and described the progress that had been made with the Purchase Fund. He also referred to the effects of increasing the annual subscription from £2 2s. to £3 3s., a step which the Council had reluctantly felt themselves compelled to recommend in view of the greatly increased cost of printing and maintenance charges generally. Proceeding then to the more particular subject of his address, "Wireless Telegraphy," he described some further developments in addition to those dealt with in the address which he gave at the opening of session 1920-21; particularly the Universal Amplifier, and the Johnsen and Rahbeck telephone. Messages were transmitted by wireless telephony from Victoria Street, and speech and music from Lewisham. The music was recorded on a phonograph in the lecture room, and was repeated to the audience from the phonographic record.

Wireless telegraphy was also dealt with by Professor J. A. Fleming, who delivered the fifth Trueman Wood Lecture. It is

just twenty-one years since the first wireless station was erected at Poldhu in Cornwall, and Professor Fleming, who called his lecture "The Coming of Age of Long Distance Wireless Telegraphy, and some of its Scientific Problems," described the advances that have been made during that period. With many of these advances Professor Fleming's own name is closely associated—particularly with the thermionic valve, which, in the words of Senatore Marconi, who seconded the vote of thanks to the lecturer, "was perhaps one of the most important contributions to the practice of long distance communication." After giving an historical account of these developments, Professor Fleming discussed in an extremely interesting way various problems still unsolved in connexion with radio-telegraphy, e.g., the methods in which electromagnetic waves are propagated round the earth, the existence of an æther, etc. The lecture, which was brilliantly delivered and illustrated by numerous experiments, was a remarkable addition to the fine series of Trueman Wood lectures.

The Industrial Fatigue Research Board was appointed in 1918 by the Medical Research Council and the Department of Scientific and Industrial Research, and its Secretary, Mr. D. R. Wilson, gave an account of the work of the Board and outlined its future policy. Investigations have been conducted in various trades with a view to ascertaining the causes of variation in output, sickness and mortality, labour turnover, lost time, and accident incidence. Such questions as the effects of temperature, humidity, lighting and ventilation on the efficiency of the worker have also been considered, and details were given of the results achieved by several particular investigators. Mr. Wilson concluded with a powerful plea for the continuance of the work of the Board in view of its importance in connexion with the increase of production, and also because of its indirect effect in bringing together employers and employed and giving each side a fresh insight into the other's difficulties.

An interesting paper, entitled "Modern Buildings in Cambridge and their Architecture," was read by Mr. T. H. Lyon, Director of Design in the University School of Architecture, Cambridge. Mr. Lyon drew particular attention to the work of William Wilkins, Basevi, the architect of the Fitzwilliam Museum, Sir Gilbert Scott,

Scott the Younger, Bodley, the new buildings for the School of Engineering, and the National Institute of Agricultural Botany. Mr. Lyon is himself the architect of one of the finest new buildings in Cambridge, the chapel of Sidney Sussex College, which exemplifies most of the features of "the grand manner"—the characteristic, according to Mr. Lyon, of all the finest architectural work in Cambridge.

Mr. Noel Heaton's paper on "The Preservation of Stone" will be found extremely useful as bringing together in one article a great quantity of information which has hitherto been scattered so broadcast as to be extremely difficult to find when wanted. He summarised all the principal processes at present in use for preserving stone, described their action and indicated generally when they could be used with advantage. As a result of his paper it would appear that a process likely to do much real good has yet to be found. "Preservative treatment," said Mr. Heaton, "should only be employed where it is certain that it can, at the worst, do no harm." He pleaded, however, for further study of the subject, and for constant exchange of experience amongst those engaged upon the problems concerned.

Towards the end of the session Mr. Heaton read a second paper, "The Production of Titanium Oxide and its Uses as a Paint Material." Although titanium is known as a "rare" metal, titanium oxide occurs in small amounts in almost all rocks: in particular it is estimated that in the neighbourhood of Stavanger, Norway, 30 million tons of titaniferous iron ore are available. Works have been established there which are now actively engaged in the extraction of the oxide. The process of manufacture by hydroelectric power was fully described, and the qualities of the oxide as a pigment were discussed. It is claimed that titanium is entirely free from the poisonous elements present in white lead; the pigment has great chemical stability, with remarkable power of resisting the weathering effects of the atmosphere; its opacity is of a high order; and on these grounds Mr. Heaton is of opinion that the pigment is destined to become one of the most widely used and valuable materials at the service of the painter.

M. Emile Cammaerts, who has perhaps done as much as any one to promote friendly feelings between this country and Belgium

and France, read a paper on "Literature and International Relations." One of the great lessons of the European War has been to teach the nations the necessity for mutual understanding, and there is no surer way to arrive at such an understanding than by study of foreign literature and art in which the temperament of a nation is most adequately expressed. He emphasised the practical importance in our schemes of education of history, geography and modern languages; he discussed the part played by journalism in affecting the outlook of peoples towards one another, and in particular he pointed out the need for foreign correspondents to have a thorough knowledge of the countries in which they reside in order that they may be able to provide correct information, and further that they should be able to present such information in a manner that will appeal to the temperament and inclinations of the people for whom they write.

Sir Walter Beaupré Townley drew attention to the possibilities of trade with the Netherlands East Indies. With their vast area of 738,000 square miles, and population of some fifty millions, these islands produce large quantities of sugar, coffee, rubber, tea, tobacco, cinchona bark, cocoa and fibres. whilst, in addition to these, rice, coconuts, corn, cassava and peanuts are grown by native agriculturists. On the other hand, there are many articles required by the Netherlands East Indies, of which the principal are textiles of all sorts, cement, iron and steel manufactures, beds, boots and shoes, glass and earthenware, drugs and chemicals, foodstuffs, mineral waters, coal, artificial manures, dyes, etc. There seems to be little doubt that a large share of this trade might well come to this country, if our merchants would take the trouble to provide what is wanted in the way that it is wanted. When German firms send out Dutch-speaking representatives, who quote prices in gilders for goods delivered at the factory, there is not much hope for the English-speaking representative who quotes in pounds sterling for goods "f.o.b. Southampton."

"Some recent Advances in the Biological Theory of Sex," was the title of a paper in which Mr. Julian Huxley brought together the results of the latest investigations into this most difficult and complicated problem. It is apparently the case that the primary distinction of sex depends on the

presence in the sexual cells of a particular enzyme, which is stored up in the X-chromosome. Again, it seems to be proved that the rate at which the male-determining hormone, or the female-determining hormone, develops varies with conditions which can be altered, so that not only primary, but also secondary sexual characters can be changed. A slide was exhibited of a guinea pig which, though born a male, was shown in the act of suckling young—not its own, however. Of course a great deal of work will have to be done before it will be possible—if ever it is—to determine the sex of the next calf or chicken; but the problem is attracting a number of investigators in different parts of the world, and fresh data are being gradually accumulated.

Under the title of "Photosculpture," Mr. Howard M. Edmunds described a process invented by himself, whereby it is possible by means of photography, to produce carved replicas in relief or in the round of any solid object. It is hardly feasible to give, in a few sentences, any adequate idea of the process. In explaining it, Mr. Edmunds exhibited a kinematograph film, which showed the method of operation very clearly. He also displayed a number of specimens of bas relief portraits and other works, produced by his methods, which seemed to indicate very considerable possibilities for the process.

Mr. Arthur Wilcock gave a full description of the process of surface printing by rollers in the cotton industry, a process that has been in use for many years in the printing of wall papers. The more usual method of printing in the textile industries, is by means of the copper roller, the pattern being engraved on its surface, intaglio fashion. In surface printing the pattern is raised above the roller. The qualities of this process are its softness of outline and general colour tone, and the finished print bears a strong resemblance to hand block work—so much so that it is sometimes mistaken for it even by members of the trade. It is, however, much less permanent than the hand block process print, by reason of its more superficial and rapid process.

In a brilliantly illustrated experimental paper, Mr. E. V. Evans discussed "Some Solved and Unsolved Problems in Gas Works Chemistry." He described first the means taken to remove naphthalene from gas by washing it in steam-distilled

oil; the method of eliminating sulphur compounds was illustrated, and the problem of getting rid of hydrogen sulphide was discussed. The dangers of carbon monoxide, which have recently been a subject of much controversy in the newspapers and elsewhere, were alluded to, and Mr. Evans contended that with four people smoking cigars in a room, as much carbon monoxide would be contained in the air as would be given out by an escape of gas which could be detected by the nose. Finally, the questions of smokeless fuel and low temperature carbonisation, were discussed, and the effect of smoke on the condition of the lungs was illustrated.

The recent report of the Departmental Committee on the Teaching of English, drew attention, among other things, to the need for proper speech training in our schools. This point was taken up and elaborated by Mr. Cloudesley Brereton, whose long experience as an Inspector of Schools, under the London County Council, enabled him to speak with authority on the subject. He pleaded for systematic training in gesture, pronunciation, intonation and rhythm. A number of special schools are already doing much good work in this direction, but in Mr. Brereton's opinion, their status is not yet adequate, and he thinks that they ought to be definitely recognised as an integral part of the national system. In fact, he pleaded for "the eventual recognition of a faculty of diction, whose constituent colleges should be united with the present colleges of music in a national Conservatoire, the whole thus forming part of a national University."

By an agreement between the British Museum and the Department of Scientific and Industrial Research, a laboratory has been provided at the Museum where experiments are conducted with a view to discovering the best means of preserving the objects exhibited there. The laboratory is under the charge of Dr. Alexander Scott, who read a paper entitled "The Restoration and Preservation of Objects at the British Museum," in which he described the work carried out by him during the last two years. The problems presented are extremely various, the objects are made of all kinds of materials, and most of them have been subjected to various chemical actions before reaching the museum. Dr. Scott discussed the treatment of objects in stone, paintings on rock, canvas and paper, enamels, and

objects in wood and sundry metals. In view of the enormous value of the contents of our museums, any sound and scientific steps taken towards their restoration and preservation deserves the warmest welcome.

Mr. Emanuel Moor gave an interesting account and demonstration of his invention, the Duplex-Coupler Pianoforte. The principal feature of the instrument is that it possesses a double key-board, the notes in the upper being an octave higher than those immediately beneath them in the lower keyboard. In this way it is possible, simultaneously, to strike two notes, which on the ordinary keyboard are ten or even twelve notes apart, with the greatest ease. Further, the two keyboards can be coupled together, so that passages in double octaves present no difficulties. By a simple device the tone of the piano can be changed into one closely resembling that of the harpsichord, and this produces an excellent effect when the performer is playing classical music originally composed for the harpsichord.

Mr. W. A. Appleton, who has been Secretary of the General Federation of Trade Unions since 1907, read a paper on "The Proper Functions of Trade Unions." He considers that these include, every problem connected with employment and unemployment, e.g., wages, hours, conditions under which employment is provided, safe-guards against accident and industrial disease, compensation where disease or accident results, and provision against unemployment. He does not include among their proper functions such objects as the provision of capital, the discovery and exploitation of markets, or the actual direction of business. While claiming for the unions the right to use their votes and influence in favour of any political party that can help them, or against any party that is hostile to them, he is opposed to their forfeiting their autonomy by tying themselves definitely to any particular party; and he strongly deprecates strikes and threats of strikes to attain political ends.

In his paper, "Certain Aspects of the Problem of Exchange Stabilisation," Mr. Oswald T. Falk criticised the authorities of the Bank of England for having maintained the bank rate at so high a figure for so long. By reducing the rate at an earlier date he maintained that the depression from which industry is suffering would have been lightened, and he urged

that there is as much justification to-day for a 2 per cent. rate as there was in the years following the Baring crisis. He considers that there are three important preliminary conditions of an attempt to stabilise exchange :—(1) A practicable settlement of the Reparation and Inter-Allied Debt problems. (2) A reduction in the size of the favourable trade balance of the United States, and the maintenance of this reduction for a considerable period. (3) A restoration of complete confidence in the ability and determination of our Government to balance the budget. Mr. Falk also criticised the Reports of the Cunliffe Committee of 1918 and 1919, and urged the necessity for appointing a new committee to consider a fresh financial policy.

The problems of protecting the coast against erosion are among the most difficult that engineers are called upon to solve. The conditions vary so much in different localities that measures which might be successful in one place are wholly unsuitable in another. Great care must be taken, also, to ensure that the steps taken to protect one part of the coast do not injure the adjoining shore. Professor E. R. Matthews, in a comprehensive paper, summarised the facts about coast erosion, so far as they are generally recognised. He described the various causes of erosion, and the different types of artificial protection works. He also dealt with the somewhat controversial subject of deep sea erosion, the formation of salt marshes, subsidence, and the findings of the Royal Commission on Coast Erosion.

The late Mr. Holman Hunt made continuous experiments in order to test the permanency of various pigments. Some of his experimental canvases came into the hands of Professor A. P. Laurie, who described the results. From these it would appear that the accepted list of pigments as used to-day is reliable with the possible exceptions of cobalt yellow in oil, pale cadmium yellow and chrome yellow. The question of the darkening of the oil was also discussed, and Professor Laurie was inclined to attribute this to the use of lead driers. These, according to the best modern practice, are now excluded from oils and varnishes.

‘The design of Repeating Patterns for Decorative Work’ was the title of a paper read by Major Percy A. MacMahon. A repeating pattern was defined as ‘a figure of such a shape that a number of them may

be fitted together so as to cover flat space without overlapping, and without leaving interstices.’ The only regular polygons which are repeating patterns are the triangle, the square, and the hexagon. These were dealt with, after a brief account of the scientific principles upon which repeating patterns can be constructed and classified; and a large number of examples were shown on the screen of other patterns derived from these three figures. Finally Major MacMahon exhibited assembled designs made from a great variety of repeating patterns. Most of these have never been utilised for practical application, and it seems possible that new sources of motifs may be suggested by them to designers.

‘The Power Resources of Ireland (Coal, Peat and Water Power)’ was the title of a paper read by Mr. George Fletcher. The annual output of Irish coal is only about 90,000 tons, while the amount imported is 4,500,000 tons. The output of the Irish mines could, no doubt, be considerably increased, although the seams are thin, and means of transport are not all that they might be; but Mr. Fletcher is of opinion that Irish peat will prove a serious rival to coal. The reserves of peat are enormous—sufficient to meet the present fuel requirements for 200 years. The drawbacks of peat are its wetness and its bulkiness. Some interesting work has recently been carried out in connexion with the maceration of peat, and an account of this was given in the paper. The Water Power Resources of Ireland Sub-Committee have investigated the potentialities of four of the most important Irish rivers, and have come to the conclusion that 500,000 W.H.P. can be continuously developed for the whole country. In order to secure efficiency and economy in the utilisation of the various sources of power, Mr. Fletcher urges that the State must take control of them, and that no time should be lost in dealing with the matter.

In a paper entitled ‘The Problem of Provincial Galleries and Art Museums, with special reference to Manchester,’ Mr. Lawrence Haward described the part played by provincial institutions in the artistic and educational life of the communities surrounding them. The Manchester Art Gallery, of which Mr. Haward is curator, has done excellent work in holding exhibitions of various kinds—as many as

sixty within the last ten years—including paintings, drawings, etchings, porcelain, pottery, printing, theatrical designs, American architecture and so forth, while numerous lectures have been given in connexion with these special exhibitions. The Manchester Education Committee have taught the children to regard a visit to a gallery as a perfectly normal experience. Mr. Haward also discussed a number of points of interest to all connected with museums and galleries, *e.g.*, the best means of showing the exhibits, the question of refusing gifts that are of poor quality, the methods of purchasing specimens, and the encouragement of a spirit of co-operation among local institutions.

III.—INDIAN AND DOMINIONS AND COLONIES SECTIONS.

The Indian Section held five meetings, the Dominions and Colonies Section four, and the two Sections jointly three. The Indian papers were:—"The Timbers of India," by Mr. Alexander L. Howard; "The Indigo Situation in India," by Professor Henry E. Armstrong; "The Need for an All-India Gauge Policy," by Mr. F. G. Royal-Dawson; and "Irrigation Enterprise in India," by Mr. F. W. Woods. The third annual Sir George Birdwood Memorial Lecture was on "Indian Art and Muhammadan Culture," the lecturer being Professor Sir Thomas W. Arnold. The papers read in the Dominions and Colonies Section were as follows:—"British Columbia: the Awakening of the Pacific," by Mr. F. C. Wade; "The Timbers of British Columbia," by Mr. William Turnbull; "New Zealand," by Lieut.-Col. Sir Thomas Bilbe Robinson; and "Tanganyika (formerly German East Africa)" by Major Sir Humphrey Leggett. The papers read at the joint meetings were: "An Imperial Airship Service," by Mr. A. H. Ashbolt; "Lignites and Brown Coals, and their Importance to the Empire," by Professor W. A. Bone, and "Imperial Wireless Communication," by Professor W. H. Eccles.

A year ago Professor S. R. Troup, in his capacity as a scientific botanist and forestry expert, dealt with the less familiar but more ornamental of India's timbers; Mr. Howard, a business man of long and wide experience, devoted his most useful paper to a practical consideration of the problem connected with the better development of this potentially valuable State asset, a

problem that is engaging and for some little time past has engaged the earnest attention of the Indian authorities. Some encouraging instances were given of the recent utilisation of the beautiful woods referred to in important buildings here, including the London County Hall and the Bank of England's new premises in Finsbury Circus. The advisability of these and the other examples mentioned being copied by the Royal Society of Arts in the renovation and redecoration of its premises was suggested and seemed to meet with general and warm approval. Professor Armstrong continued the rather melancholy "story of indigo," begun by him in the paper he read three years ago. He now reaffirmed with greater emphasis than ever his belief in a secure future for the natural dye. Not only has indigo a markedly higher value as a dyestuff than indigotin pure and simple, but it may well happen, he pointed out, that not a few natural dyestuffs may once more be in demand because of the difficulty of obtaining the raw materials of the artificial substitutes. He laid stress on the extraordinary value of an experimental inquiry, such as Mr. Davis has initiated, into the requirements of a leguminous plant so typical as that yielding indigo, and deplored the discontinuance of the work of so exceptionally capable an inquirer. "Agriculture," Professor Armstrong said, "is the chief industry of the country, yet it is to be deprived of scientific aid when it is in sorest need of help." On this point he had the powerful support of the Chairman of the meeting, Sir Thomas H. Holland, who said that it would be for the benefit of India if the discussion of that evening helped the Government to re-open the question afresh. In urging the need for an All-India gauge policy, the ex-Chief Engineer to the Indian Railway Board submitted two questions for consideration: (1) Is the perpetuation of the dual standard desirable in the public interests and (2) if not, is alleviation of the evil financially practical? He answered the first question in the negative and the second in the affirmative, arguing that to secure continuity of policy in the direction of unification the construction of new metre gauge lines should be restricted by legislation. Sir William M. Acworth, chairman of the representative committee which the year before last, at the request of the Government, searchingly inquired into the administration of Indian

railways, made a weighty contribution to the discussion. He urged that what is wanted is a "policy" and not legislation. That policy ought to be threshed out on the understanding that it would be permanent and not interrupted by financial opportunism. Sir Thomas Arnold reminded his distinguished audience that the modern historian, particularly if he be a Frenchman or a German, throws his net wide to gather matter for his account of any period and is no longer content to rely merely on the written word of the chronicler. One of the results of this wider outlook has been the use of illustrations even in serious works of historical research. This new line of investigation was followed by Sir Thomas Arnold in his scholarly and admirably-illustrated lecture on "Hindu Painting and Muhammadan Culture." The study of India, as the lecturer observed, is our peculiar domain; no nation possesses so rich a store of material for the purpose as exists in the records and manuscript documents of all kinds lying in the great collections of this country; written and printed sources are indeed receiving attention, but hitherto little use has been made of pictures as aids to historical research, though they have not been entirely unregarded by students of art. Sir Thomas Arnold mentioned that he selected his subject as being one which he knew "would have gained the approval of the great man in whose memory this annual lecture was instituted." The interest of the occasion was enhanced by the presence in the chair of Viscount Peel, this being one of the earliest, if not the first of his public appearances since his appointment as Secretary of State for India. The ex-Governor of Bengal, Lord Ronaldshay, also took part in the proceedings.

The exhaustive paper on "Irrigation Enterprise in India" consisted mainly of a searching examination of the "greatest project for perennial canal irrigation of modern times," the Sukkur Barrage Scheme, which aims at irrigating 5,300,000 acres, rather more than the total culturable area of Upper and Lower Egypt, and is estimated by the Government to cost some twelve millions sterling, though according to Mr. Woods, it will involve an expenditure of not less than £17,000,000. As the engineer who for some years has controlled the administration of the magnificent system of "canal" irrigation in the Punjab—from

a material point of view one of the greatest achievements of British rule—Mr. Woods holds that the proposed undertaking is unnecessary, and he supports this contention by pointing to other perennial canals in the peninsula that are fed from their parent rivers without the help of barrages. Although the Sind proposal has, subject to compliance with certain financial arrangements, received the approval of the Secretary of State, Mr. Woods urges that the question should be re-opened and submitted to the adjudication of a committee of experts.

In his brilliant paper on the awakening of the Pacific, Mr. Wade asked the question what is the part which the prosperous and richly-endowed province he so ably represents in the Motherland—British Columbia—is likely to play in the "most momentous event of the Twentieth Century?" The whole answer, he said, depends upon the resources which she is able to contribute to the giant development, particularly upon the stores of energy which she is able to employ. The extent of the resources of all kinds is indeed formidable—timber, coal, water-power and iron, not to mention climate and sunshine. Vancouver Island has been called the "Madeira of the Pacific"; Mr. Wade terms British Columbia the "Riviera of Canada." One of the prominent activities of the province, the development of its forest land, estimated at 149,000 square miles, was described in detail later in the session by Mr. William Turnbull, the Timber Commissioner to the Government of British Columbia. Sir Thomas Robinson, in his paper, said little about the economic problems of New Zealand, which have received attention in previous sessions, confining himself, as a visitor, mainly to a very appreciative account of the many attractions which that picturesque and inviting country offers to tourists, who, it seems, are visiting the Dominion in increasing numbers.

A feature of Sir Humphrey Leggett's paper, which may be regarded as complementary to the one he contributed to the Society a few years ago—"The Economic Development of British East Africa and Uganda"—was the earnest plea it contained for a definite policy in the administration of the extensive mandated territory, Tanganyika, which, as a result of the War, has passed into our hands and whose area equals that of France and Germany combined. Sir Humphrey Leggett described

the new possession as a country destined for a carefully balanced combination of plantation development and native crop production and, except for a comparatively small patch or two, as not suited for European settlement on Colonial lines, namely, farming and ranching. The present population of the British group of East African countries, including the recent addition dealt with, is 12,000,000. In a hundred years "with the *Pax Britannica*, the British pharmacopœia and good government" it may be estimated at 50,000,000. "The Roman Empire in Africa covered 600 years of time. In less than half that period tropical Africa will have her hundreds of millions of British native subjects." Will they, Sir Humphrey asked, be a blessing or a curse? What is done during the next decade, he said, will decide the answer.

Mr. Ashbolt devoted a portion of his able and comprehensive paper on an imperial airship service to a review of the situation created by the decision of his Majesty's Government to eliminate the dirigible from the scheme of defence. He recommended that the threatened vessels and plant be utilised experimentally for two years, contending that financially the idea was feasible provided the Governments concerned combined to furnish a subsidy of £500,000, and that part of the mails were conveyed in the airships. Major-General Sir William Brancker, however, seemed to doubt whether any subsidy would be necessary, in view of the high fares for passengers that might be looked for. He declared that he absolutely believed in the airship. The views of Mr. Holt Thomas, who was abroad at the time, were at his request communicated to the meeting. He also expressed his belief in airships for commerce, but was rather averse from plunging into a definite service round the world until further data have been obtained. In the valuable paper read by Professor Bone, it was shown that whilst Great Britain itself is almost destitute of lignites (the well-known Bovey Tracey deposit in Devonshire being the only important one), the solution of the various technical difficulties associated with their efficient use is of especial importance to Canada and Australia, as well as to other parts of the Empire. Professor Eccles's important paper, which has attracted an unusual amount of public attention, contained what he himself called a plain statement of the facts, historical,

scientific and technical, which ought to be in possession of those wishing to form their own opinion upon the proposal to erect an Imperial Chain of Wireless Stations. The President of the Empire Press Union, Viscount Burnham, occupied the chair, and Senator Marconi was one of those who made interesting contributions to an exceptionally good discussion.

IV.—CANTOR LECTURES.

The first course, "Processes of Engraving and Etching," was delivered by Mr. Arthur M. Hind, Slade Professor of Fine Art in the University of Oxford. The three lectures were devoted respectively to wood-cut, line-engraving, and etching. In each case he described the process and its origin, and showed examples of the work from its earliest to its latest developments.

Mr. C. Ainsworth Mitchell gave the second course on "Inks." In the first lecture, which was largely historical, he traced back the history of ink manufacture to about 2,000 B.C. in China, where it was conducted on much the same lines as were followed in this country up to comparatively recent times. In his subsequent lectures he described the nature and manufacture of many kinds of ink, and incidentally showed how an expert knowledge of the composition of inks had proved useful in trials for forgery and other crimes.

Professor Alan F. C. Pollard delivered the third course on "The Mechanical Design of Scientific Instruments." This is a subject which does not seem to have received as much attention as it deserves in this country, and the lectures were much appreciated by the large audience who attended them. Professor Pollard showed some extremely beautiful but simple designs, and explained the principles on which the manufacture of scientific instruments should be based.

The fourth and final course was given by Mr. Guy Radcliffe on "The Constituents of Essential Oils." The methods of growing the raw material and of the various processes of manufacture were fully described, and the lecturer strongly urged the necessity for further research in the subject. Nearly all the materials from which essential oils are procured can be obtained within the British Empire, and, in Mr. Radcliffe's opinion, the manufacturers of this country have it in their power to secure the trade of the world.

V.—SHAW LECTURE.

Sir Thomas Oliver, in delivering the Shaw Lecture, chose as his subject "Alcohol in relation to Industrial Hygiene and Efficiency." He discussed the physiological effects of alcohol upon the brain, its value as a food, and the connexion between week-end drinking and the loss of time and increase of accidents caused by this habit. Reference was made to the great experiment in Prohibition being carried on in the United States at present. This is being watched with great interest by scientific observers, and the results of a trial on such an enormous scale will go far to decide the question whether, on the whole, alcohol is beneficial or injurious to the worker.

VI.—DR. MANN JUVENILE LECTURES.

It was announced in the last Annual Report that the Society had received, under the terms of the will of the late Mrs. Charlotte Elizabeth Mann, a legacy of £1,000, to be devoted in the first instance to the institution of a course of lectures to be known as the "Dr. Mann Juvenile Lectures." The first course under this Trust was delivered during the Christmas recess by Dr. William Reginald Ormandy, his subject being, "Clay—What it is—Where it comes from—and What can be done with it." He described the origin of clay, and its principal characteristics, and gave some account of the history of the principal industries in which it is used. The lectures were illustrated with a number of experiments, whilst two employees from Messrs. Doulton and Co.'s works gave an exhibition of the use of the potter's wheel in throwing various forms of pottery.

VII.—ALBERT MEDAL.

The Albert Medal of the Society for 1922 has been awarded by the Council, with the approval of the President, H.R.H. The Duke of Connaught and Strathearn, K.G., to Sir Dugald Clerk, K.B.E., F.R.S., D.Sc., LL.D., in recognition of his important contributions, both theoretical and practical, to the development of the internal combustion engine, which in its later forms has rendered aerial navigation possible, and is also so extensively employed in the motor car, and in the submarine and for many other purposes.

Sir Dugald Clerk's work may be divided into two categories—his specific inventions

and his general scientific and educational work. Of his actual inventions, no doubt the best known and the most far-reaching, is that of the Clerk cycle, in which an explosion is obtained at every outward stroke of the piston, which has been, and still is, very widely employed in various guises. In addition to this, his name is well known in connexion with many other inventions relating to the internal combustion engine, such as the flame starter for gas engines and the platinum grid igniter.

Brilliant and valuable as his inventions have proved, it is his scientific and educational work which has made his name so deservedly famous, and has been so largely responsible for the rapid development of the internal combustion engine. Successful invention implies wide imagination coupled with sound judgment; scientific and educational work such as Sir Dugald Clerk has done, and is doing, requires these qualities and many more. At the time when he first devoted his attention to the internal combustion engine, little was known of the true principles involved. Under his handling, vague superstitions and purely empirical rules vanished before logical and reasoned theoretical treatment.

He set himself the task both of searching out the true principles on which all internal combustion engines operate and of teaching these principles to others. For these two tasks no man could be better fitted; his clear thinking enabled him very quickly and surely to sift out the essential problems and his brilliant research work to solve them. Still more valuable, his peculiarly lucid expositions of his discoveries and of his lines of thought, have enabled others, far less gifted, to follow him. Indeed, nearly all the important developments of the internal combustion engine during the last thirty years are the direct outcome of Sir Dugald Clerk's work and teaching.

Born in 1854 it was in 1878 that he produced the first gas engine operating on the now well-known Clerk cycle. After this, for some years he devoted himself exclusively to the study of the internal combustion engine, and the fruits of his investigations he published in 1886 in a book on "The Gas Engine," which has become a standard work on the subject. During this early period, he read several papers, the most important of which was one on the theory of the gas engine, read in 1882

before the Institution of Civil Engineers, for which he was awarded the Watt Medal; in this paper he discussed the theory of compression and proved definitely and numerically, the relative improvement in thermal efficiency to be gained thereby. The paper, in fact, established the well-known air standard of efficiency, a standard which holds to this day as the basis of comparison for all internal combustion engines. This paper was followed in 1886 by a second and almost equally important paper on the explosion of homogeneous gaseous mixtures, also read before the Institution of Civil Engineers, and for which he was awarded the Telford Premium. In 1887, he produced what he termed a flame injection engine, an engine which, though abandoned at the time, was revived in a modified form six years later by Dr. Diesel and has since become famous as the Diesel engine. In 1904, also, he delivered before the Institution of Civil Engineers the first James Forrest Lecture on the internal combustion engine; this was followed in 1907 by another very valuable paper on the limits of thermal efficiency in internal combustion engines, in which he showed, for the first time, that the loss of heat to the cylinder walls is by no means so serious as had previously been supposed. This paper was awarded the Telford Medal. In 1908 he was made a Fellow of the Royal Society, largely in consequence of his classic paper on the specific heat of the working fluid in internal combustion engines, read before that Society in 1906. From then on to the present day, he has made numerous investigations, and read many important papers defining the state of the art; and always pointing the way to further developments, probably the most notable of these being his Gustave Canet Lecture, before the Junior Institution of Engineers in 1913. During the period of the War, he worked indefatigably on numerous technical Committees, where his experience and advice proved invaluable. Among other appointments he held, was that of Director of Engineering Research to the Admiralty, 1916-1918. Included in the many honours conferred upon him, in addition to his Knight Commandership of the British Empire and Fellowship of the Royal Society, are those of D.Sc. of Manchester and of Leeds, and LL.D., both of St. Andrews and Glasgow.

While his scientific work has done more than that of any man living, to promote

the development of the internal combustion engine, the charm and power of his personality have instilled enthusiasm into many of the younger generation, thus providing a host of disciples who ensure that this development will continue along the lines he has so ably laid down.

VIII.—MEDALS FOR PAPERS.

Nine medals have been awarded for the papers read before the Society during the present session—five for papers read at the Ordinary Meetings, one for those read in the Indian Section, one for those read in the Dominions and Colonies Section, and two for those read at Joint Meetings of the Indian and Dominions and Colonies Sections.

The awards are as follows:—

Papers read at the Ordinary Meetings:—

HOWARD MAURICE EDMUNDS, "Photo-Sculpture."

EDWARD VICTOR EVANS, O.B.E., F.I.C., Chief Chemist, South Metropolitan Gas Company, "Some Solved and Unsolved Problems in Gas Works Chemistry."

W. A. APPLETON, C.B.E., Secretary to the General Federation of Trade Unions, "The Proper Functions of Trade Unions."

JOHN FRANCIS CROWLEY, D.Sc., B.A., M.I.E.E., "The Use and Advantages of Electric Power in the Factory, as illustrated by its Application to the Jute Industry."

LAWRENCE HAWARD, M.A., Curator of the City Art Gallery, Manchester, "The Problem of Provincial Galleries and Art Museums, with special reference to Manchester."

Paper read in the Indian Section:—

PROFESSOR HENRY E. ARMSTRONG, Ph.D., LL.D., D.Sc., F.R.S., "The Indigo Situation in India."

Paper read in the Dominions and Colonies Sections:—

FREDERICK COATE WADE, B.A., K.C., Agent-General for British Columbia, "British Columbia—The Awakening of the Pacific."

Papers read at Joint Meetings of the Indian and Dominions and Colonies Sections:—

PROFESSOR WILLIAM ARTHUR BONE, D.Sc., Ph.D., F.R.S., "Lignites and Brown Coals and their Importance to the Empire."

PROFESSOR W. ECCLES, D.Sc., F.R.S., M.I.E.E., "Imperial Wireless Communication."

For many years it has been the practice that no medals should be awarded to members of the Council, or to readers of papers, who have previously received medals from the Society. Acting on this rule the Council were precluded from considering the following papers:—

MAJOR PERCY A. MACMAHON, R.A., LL.D., Sc.D., F.R.S., "The Design of Repeating Patterns for Decorative Work."

NOEL HEATON, B.Sc., "The Preservation of Stone," and "The Production of Titanium Oxide and its use as a Paint Material."

PROFESSOR A. P. LAURIE, M.A., D.Sc., F.R.S.E., H.R.S.A., "The late Mr. Holman Hunt's Experiments on the Permanency of Artists' Oil Colours."

PROFESSOR ERNEST R. MATTHEWS, "Coast Erosion and its Prevention."

GEORGE FLETCHER, Department of Agriculture and Technical Instruction for Ireland, "The Natural Power Resources of Ireland (Coal, Peat, Water Power)."

MAJOR SIR HUMPHREY LEGGETT, D.S.O., R.E., "Tanganyika Territory (formerly German East Africa)."

ALFRED HENRY ASHBOLT, Agent-General for Tasmania, "An Imperial Airship Service."

The Council desire, however, to express their appreciation of these papers.

IX.—OWEN JONES PRIZES.

With the kind assistance of the Director of the Victoria and Albert Museum, the Council again in 1921 arranged for a competition of students from Schools of Art in accordance with the terms of the Owen Jones Trust.

The subjects of competition were:—

BOOK PRODUCTION AND ORNAMENTAL LEATHERWORK: including Covers and Lining Papers for Bookbinding, Title Pages, Lettering and Printing, Posters, Trade Labels and Advertisements.

METALWORK: including work in Precious Metals, Ironwork, Jewellery, Enamelling, etc.

WALLPAPERS, and other Mural Decorations.

TEXTILES: including Damasks, Brocades for Decoration and Furniture, Printed Fabrics for Hangings, Vestments and Church Fabrics (including

Altar Frontals, etc.), Figured Velvets and Figured Muslins.

Two hundred-and-thirty-seven designs or works were submitted by 181 competitors from 36 schools. These figures show a marked increase as compared with those of 1920, when 94 designs were submitted by 63 competitors from 17 centres. The judges also reported a considerable advance in the standard of the candidates' work.

In accordance with the recommendation of the Judges the Special Prize of £20 was divided equally between H. S. Evans, School of Art and Design, Nottingham, and Miss E. Suthons, Municipal School of Art, West Bromwich; while, in view of the high standard of work as well as the large number of entries, seven ordinary prizes were awarded instead of the six originally offered by the Council.

The work was exhibited to the public at the Victoria and Albert Museum from July 21st to September 17th.

Full information of the conditions of the competition in 1922 were published in the *Journal* of January 6th last (p. 145).

X.—EXAMINATIONS.

The examinations form an important and rapidly growing branch of the Society's work. A number of large firms now encourage their employees to enter for them, and many of them grade their junior staffs according to the results of the examinations. This increasing recognition of their value is naturally having a marked effect on the number of entries. At the March-April examinations there were 22,160 entries, and at the May-June examinations 38,172 entries, making a total of 60,332, an increase of 5,136 over the corresponding figure for 1921. In order to show their growth the figures are given for the last four years, for 1914, which was then the record year, and also for 1916, which shows the effect of the war on the entries:—

Year.	Number of entries.
1914	37,974
1916	25,968
1919	34,173
1920	54,010
1921	55,182
1922	60,332

The following subjects were added to the Syllabus in 1922:—In Stage III., "Insurance Law and Practice" and "Railway Economics;" in Stage II., "History of Inland Transport in Great Britain." Papers

in "Commercial Law" and "Company Law" were also set in both Stages II. and III., instead of in Stage III. only, while papers in "Theory and Practice of Commerce" were set in all three stages instead of in Stages III. and II. only.

Two new Group Certificates for Shorthand Typists and Shipping Clerks were also instituted. Particulars of these are given in the syllabus of examinations.

The liberality of the Worshipful Company of Clothworkers has enabled the Council, as in past years, to offer the usual silver and bronze medals. These medals are very highly valued by the successful candidates, and they contribute not a little to maintain the high standard of the examinations.

The results of the First Division of the Examinations, held in March-April, have already been communicated to the candidates; and those of the May-June Division will be announced as soon as possible.

A report giving full details of the year's Examinations will be published in the *Journal*, as usual, at a later date.

XI.—ORAL EXAMINATIONS IN MODERN LANGUAGES.

The Oral Examinations are still in progress in various parts of the country. Particulars will be given in the annual report on the Examinations.

XII.—PETER LE NEVE FOSTER PRIZE.

The Council decided to offer the Peter Le Neve Foster Prize of £10 and the Society's Silver Medal (founded in commemoration of Mr. Peter Le Neve Foster, who was Secretary of the Society from 1853 to 1879) for an essay on "The Mineral Resources of China." An announcement to this effect was published in the *Journal*,* and December 31st, 1921, was fixed as the date by which entries were to be received. The essays were referred to an adjudicator appointed by the Council, and on his recommendation the prize was awarded to Mr. C. Y. Wang, Consulting Mining Engineer, of Hankow.

XIII.—NEW COUNCIL.

Mr. Alan A. Campbell Swinton has been nominated a Vice-President by His Royal Highness the President, in view of the special services which he has rendered to

the Society by occupying the office of Chairman of the Council for four years and by the very great interest he has taken in initiating and promoting the fund for purchasing the freehold of the Society's House.

The Vice-Presidents retiring under the ordinary regulations are: Sir William H. Davison (who is nominated a Treasurer), Sir Robert A. Hadfield, Lord Leverhulme and Sir Aston Webb. In their places the Council recommend Lord Inchcape, Senator Marconi, Lord Montagu of Beaulieu, and Mr. John Slater.

The four Ordinary Members of the Council retiring are: Sir William H. Clark, Mr. John Slater (who is recommended as a Vice-President), Mr. Charles B. L. Tennyson and Professor J. M. Thomson. In their places the Council recommend Sir Dugald Clerk, Sir Thomas Holland, Sir Humphrey Leggett, and Sir Frank Warner.

XIV.—OBITUARY.

A number of distinguished Fellows have died during the last twelve months.

The Earl of Halsbury, who reached the great age of 98, was at one time a member of the Council and a Vice-President of the Society.

The Earl of Ducie, the "Father" of the House of Lords, also served on the Council and was a Vice-President of the Society.

The Right Hon. Frederick Huth Jackson was a director of the Bank of England and a high authority on Finance.

Sir Alexander Hargreaves Brown had been a member of the Society since 1871 and took considerable interest in its proceedings.

Sir William Edward Garforth, the well-known mining engineer, was awarded in 1911 by the Council a gold medal under the Fothergill Trust "in recognition of his efforts to perfect and secure the adoption of rescue apparatus in mines."

Sir Frederic W. R. Fryer was a member of the Indian Section Committee and a constant attendant at the meetings of the Indian Section, at which he frequently spoke.

Mr. T. N. Nacheapa Chetty was a well-known banker and philanthropist. At his death his son, Mr. T. N. Muthiah Chetty, contributed a sum of £500 to the fund for purchasing the Society's house.

Among other notable Fellows who have died during the year may be mentioned

*See *Journal*, April 1st, 1921, Vol. xlix., p. 229.

Sir Samuel Davidson, Sir George John Smith, Sir Edward Charing Wills, Mr. Ralph Brocklebank, Mr. Edward Hopkinson, M.P., the eminent engineer. Sir Henry Francis Barker, and Mr. W. J. Starr. The well known Russian metallographist, Professor Dimitris Tschernoff, who was elected an Honorary Corresponding Fellow of the Society in 1909, also died within the year.

Notices of the above named, and of other Fellows who have died during the last twelve months, will be found in the columns of the *Journal*.

XV.—FINANCE.

The income and expenditure account for 1920 showed a balance, being excess of income over expenditure of £548 15s. 2d. Unfortunately, the corresponding figure for 1921 showed an excess of expenditure over income of £405 15s. This deficiency is, to a large extent, due to the doubling of the *Journal* postage, which meant an additional expenditure of nearly £400. The annual subscriptions in 1921 amounted to £7,005, an increase of nearly £300 over the figure for 1920; but there was a very great decrease in the sum received for life composition fees. In 1920 this figure was £1,550—by far the largest amount ever received under this head; but in 1921, by which time the general depression throughout the country was making itself felt, it fell to £520.

The cost of the *Journal* fell from £4,541 in 1920 to £4,030 in 1921, and it is confidently expected that this sum will be similarly reduced again in 1922. It is also hoped to make further considerable reductions in the cost of printing in connexion with the Examinations. Last autumn the Council purchased a Gammeter Multi-graph Printing Machine, at a cost of £355. With this it will be possible to print most economically a great deal of the stationery, etc., required for the Examinations, as well as much miscellaneous work, such as invitation cards for meetings, Council Agenda, etc.

Owing to the large increase in the number of candidates for the examinations, it was increasingly difficult to carry out the work of handling from 50,000 to 60,000 papers in the very limited space available in the Society's house. In September last an opportunity presented itself of leasing three suitable rooms at No. 18, John Street, and the Council decided

to take them at a rental of £200 per annum. This amount will be met by the increased fees of candidates, while the room in the Society's house hitherto devoted to the Examination work, will be available as a smoking room for Fellows.

It has also to be borne in mind that, as the Society has now acquired the freehold of their house, the rent (£800 per annum) will be no longer payable. When all these points are taken into consideration, the Council hope to show a satisfactory income and expenditure account for 1922.

THE CHAIRMAN (MR. ALAN A. CAMPBELL SWINTON, F.R.S.) moved the adoption of the Report. The most interesting matter in it he thought was that relating to the purchase of the building and the suggested improvements, and he would give them some idea of what it was proposed to do. So far as the meeting room was concerned, they hoped to make it more comfortable by removing the platform and raising the floor, and having a gangway in the centre at a higher level. The whole of the seats would be at a more or less uniform slope, and instead, as at present, of people in the front having to look up to the speaker, they would look down upon him. When experiments were shown at the meetings, it was very difficult to demonstrate them satisfactorily with the present arrangement of the platform. The Council also proposed to have new seats. They had visited several Institutions, and the seats they intended to adopt were based upon those in use at the Society of Antiquaries, which were of the Chippendale period. This form of seat would be slightly altered in order to make it still more comfortable. The meeting room was to be re-decorated and the ceiling painted white. The present electric chandeliers would be taken down and alabaster bowl reflectors used instead. The pictures would be cleaned and the portraits re-arranged, those of the first two Presidents of the Society being restored to their original places. The lower part of the walls, under the Barry pictures, would be painted a much lighter colour. Considerable alterations would also be made in the lower rooms and the entrance hall would be made more imposing. The staircase would end at the first floor, and a roof would be put in on a level with the present gallery, which would give them an additional room for storage purposes. The library would be restored to the condition it was in as built by the Brothers Adam. The present projecting cast iron cases, made for the reception of models, would be removed and supporting columns put in their place. This would make the library much larger and there would be additional light from the side windows, at present blocked by the cases. Cloak room and lavatory accommodation for ladies would also be provided.

These were the main changes. At present they could not afford to spend too much, but at a later stage they hoped it would be possible to re-decorate the Council Room and other rooms throughout the building. Another matter in the Report he wished to refer to was the paragraph relating to Sir Dugald Clerk, which was written by a disciple of his, one of our cleverest engineers and the designer of the engines used in the Tanks—Mr. H. Ricardo, to whom they were greatly indebted for the admirable account of Sir Dugald Clerk's work.

SIR PHILIP MAGNUS, Bt., M.P., said he had very great pleasure in seconding the adoption of the Report. He agreed with the Chairman that one of the most interesting matters referred to in the Report was the fact that the Society had at length obtained possession of the building in which it had been housed for so many years. He felt sure the alterations it was proposed to make would be very much to the advantage of the Society and to the general body of Fellows. He was glad to hear that the seats in the meeting room would be similar to those at the Society of Antiquaries. The Report he said, gave an extremely good resumé of the excellent papers and lectures which had been given before the Society. The Report dealt with a great many matters of scientific and technological interest. The meetings had been well attended, and it was very satisfactory to notice that the papers had been followed by discussions in which experts thoroughly acquainted with the subjects had taken part. To anyone interested in the application of science to industry, he knew of nothing more educational than the *Journal* of the Society. Another subject in which he took a more distinct and particular interest, was the Examinations, the entires for which, as stated in the Report, had risen from 37,974 in 1914, to 60,332 in 1922. It was now close on fifty years since the Society first endeavoured to arouse interest in the application of science to industry and in the details of commerce, by encouraging instruction in its applications by means of examinations. It certainly was the first Society in this country to introduce what are known as technological examinations — examinations which dealt with applications of science to the applications of industrial concerns. These examinations were afterwards taken over by the City and Guilds of London Institute, and since that time the Society had extended its examinations in commercial subjects, and had succeeded in popularising commercial science all over the country, so that commerce was now regarded on exactly the same lines as other University subjects which qualify for a degree. The Examinations Committee, of which he had the honour to act as Chairman, were always considering means for enlarging the scope of the examinations, and he could assure the Fellows that they were

constantly receiving applications for increasing the number of subjects.

The adoption of the Report was then agreed to.

THE CHAIRMAN proposed a cordial vote of thanks to Mr. G. K. Menzies (the Secretary), Mr. S. Digby (the Secretary of the Indian and Dominions and Colonies Sections), Mr. George Davenport (the Chief Clerk), Mr. J. H. Buchanan (the Accountant and Examinations Officer), and to the other officers of the Society for their services during the year. As mentioned by the previous speaker, they had had some most excellent papers, and their hearty thanks were due to Mr. Menzies and to Mr. Digby for obtaining these.

THE SECRETARY returned thanks for this expression of confidence in himself and in the other officers of the Society.

The ballot having remained open for half-an-hour, and the scrutineers having reported, the CHAIRMAN declared that the following had been elected to fill the several offices. [The names in *italics* are those of Fellows who have not, during the past year, filled the office to which they have been elected.]

PRESIDENT.

H.R.H. The Duke of Connaught and Strathearn, K.G.

VICE-PRESIDENTS.

Lord Askwith, K.C.B., D.C.L.

Sir Charles Stuart Bayley, G.C.I.E., K.C.S.I.

Lord Bearsted

Sir George T. Beilby, LL.D., F.R.S.

Sir Thomas Jewell Bennett, C.I.E., M.P.

Lord Blyth.

Edward Dent, M.A.

Peter MacIntyre Evans, M.A., LL.D.

*Field-Marshal Earl Haig, K.T., G.C.B., O.M., G.C.V.O., K.C.I.E.

Lord Inchcape, G.C.M.G., K.C.S.I., K.C.I.E.

Sir Herbert Jackson, K.B.E., F.R.S.

Senator Guglielmo Marconi, G.C.V.O., LL.D., D.Sc.

Brig.-Gen. Lord Montagu of Beaulieu, K.C.I.E., C.S.I.

Viscount Northcliffe.

Major Sir Francis Grant Ogilvie, C.B., LL.D.

Hon. Sir Charles Algernon Parsons, K.C.B., LL.D., D.Sc., F.R.S.

Lord Sanderson, G.C.B., K.C.M.G.

John Slater, F.R.I.B.A.

James Swinburne, F.R.S.

*Alan A. Campbell Swinton, F.R.S.

Carmichael Thomas

Sir Philip Watts, K.C.B., LL.D., F.R.S.

*Sir Henry Trueman Wood, M.A.

ORDINARY MEMBERS OF COUNCIL.

Sir Dugald Clerk, K.B.E., D.Sc., LL.D., F.R.S.

Charles Frederick Cross, F.R.S.

*Nominated by H.R.H. the President.

Professor John Bretland Farmer, M.A., D.Sc.,
F.R.S.

John Somerville Highfield, M.Inst.C.E., M.I.E.E.
Sir Thomas Holland, K.C.S.I., K.C.I.E., D.Sc.,
F.R.S.

Major Sir Humphrey Leggett, D.S.O., R.E.

Major Percy A. MacMahon, R.A., LL.D.,
Sc.D., F.R.S.

Sir Philip Magnus, Bt., M.P.

Ernest H. Pooley, M.A., LL.B.

Sir George Sutton, Bt.

Sir Frank Warner, K.B.E.

Sir Alfred Yarrow, Bt., M.Inst.C.E.

TREASURERS.

Sir William Henry Davison, K.B.E., D.L.,
M.P.

William Henry Maw, LL.D., M.Inst.C.E.

SECRETARY.

George Kenneth Menzies, M.A.

On the motion of the CHAIRMAN a vote of thanks to the Scrutineers was carried unanimously.

MR. CARMICHAEL THOMAS proposed a very hearty vote of thanks to the Chairman, and was sorry that this was the last occasion on which he would act as Chairman of the Council. He had held the office for four years, and during the past century there had only been three similar cases of double re-elections. It was a source of great regret to the Council that they now had to lose Mr Campbell Swinton as Chairman, and he felt sure all would agree that he deserved a very hearty vote of thanks for his valuable services.

MR. JOHN SLATER, F.R.I.B.A., seconded the motion. Mr. Campbell Swinton, he said, although a very busy man, had done an enormous amount of work for the Society, and they owed him their very cordial thanks for his services as Chairman, and for all that he had done in connection with the fund for purchasing the Society's House.

THE CHAIRMAN said it had been a great pleasure to him to act as Chairman of one of the most charming of Councils. He was also glad to be of assistance in raising funds to purchase the freehold of their historic house. He would like to point out though that the thanks of the Society were also due to Mr. Menzies for finding them their anonymous benefactor. This was the last time he would act as Chairman of the Council, and it would also be the last time they would meet in the room in its present condition. The renovation would be completed by November, when he hoped the room would have a more attractive appearance.

The meeting then adjourned.

BRISTLE TRADE OF TIENSIN.

Bristles constitute one of the leading items of export from Tientsin. According to the Chinese maritime customs returns, the exportation of bristles from Tientsin in 1919 amounted to 2,300,667 pounds, valued at 1,912,972 haikwan taels, and in 1920 to 2,515,733 pounds, valued at 2,305,850 haikwan taels. The conversion of these tael values into foreign currency is likely to be misleading, because of the violent fluctuations in exchange in the years 1919 and 1920. The rate used by the Chinese Maritime Customs in actual entries varies week by week. For this reason the best index of the volume of the business is to be found in quantities rather than in values.

The bulk of the bristles from Tientsin go to the United States, but England, France and Japan share a portion of the trade.

Hotou, at the terminus of the East Canal, is a large distributing centre of bristles in North China. Here bristles are brought from Tsunhua, Yungping, regions outside the Great Wall, and Manchuria, and after being sorted and graded are sent to Tientsin by junk or railway. Paotingfu and Peking are other large bristle centres, whence shipment is made to Tientsin, either by railway or from Paotingfu by river. It is believed that the Paoting article is slightly inferior in quality to the Hotou bristles.

From a report by the United States Consul at Dairen, it appears that there are several ways of working the bristle business for export from Tientsin. The principal amount is exported in assortments of 55 or 66 cases, but other assortments containing 80, 40, or 100 cases are sometimes made to meet special demands. Of these usual assortments, the 55-case is considered the most desirable, because it contains a greater amount of long-length bristles. One of the usual type of 55-case assortments contains about the same number of cases of bristles of each length from 2½ inches to 5½ inches. The bristles are packed in cases of 110 pounds net, including the weight of string used in tying the bundles, and all the bristles in a given case are the same length, but in an assortment the lengths vary usually by ¼-inch steps—for instance, 2½ inches, 2¾ inches, 3 inches and upward. The preceding remarks regarding the variation in length and packing apply to all assortments.

The 66-case assortment usually sells for a much lower price than the 55, averaging perhaps about 40 to 50 per cent. of the price obtained for the 55. This is due to the fact that the 66-case assortment contains a large number of cases of short lengths, principally 2½ inches long, and lesser amounts of the extra long bristles. It is generally understood that the greater the length, the higher the price. The basis of sale of an assortment is usually an average price per pound for the entire net weight of bristles in that assortment. Bristles are purchased

from the producers in piculs (1 picul = 133 pounds) and sold to dealers abroad by pounds.

It is customary to grade the bristles according to elasticity, stiffness, colour, cleanliness and solidity. Of the bristles exported from Tientsin, the best quality comes from Mukden. As a rule, these are much more stiff and elastic, thicker, with less taper of individual hair, and of much blacker colour. After these come the Peking and Paotingfu quality, which, as a rule, are not so stiff, and have more taper of individual hair. The Paotingfu bristles are generally considered somewhat inferior to the Peking, but as Peking is a better known place and is a collecting centre for this commodity, it frequently happens that the Paotingfu dealers take their cargo to Peking and sell it as Peking quality, with or without mixing with actual Peking bristles.

The best quality of black Tientsin bristles is made by either selling straight Mukden bristles or by blending suitable proportions of Mukden with Peking or Paotingfu. A fair amount of Mukden bristles when mixed in with the Peking or Paotingfu quality adds materially to the general stiffness, appearance, and elasticity of the bristles bundled as a whole.

Bristles from Shantung Province are also exported from Tientsin. One of the principal sources of supply for the Shantung bristles is in the vicinity of Weihsien, and Shantung bristles brought to Tientsin frequently come from this region. The principal point of export, however, for Shantung bristles, is Tsingtau. Comparison of the Shantung (Weih-sien) bristles with the Peking or Mukden quality will show that the Shantung are considerably finer with more taper of individual hair, are softer, and of poorer colour, and as a result of these characteristics the Shantung bristles bring lower prices than the northern grades.

There are several methods of securing bristles properly packed in assortments for export, including:—

(1) The purchase of complete, fully dressed, ready-packed assortments from regular Chinese bristle contractors, or from the compradore of the firm. As a rule, the quality of this cargo is guaranteed by the seller to the buyer.

(2) Partial assortments of ready-dressed cargo may be bought from dealers, and the firm may buy a few cases here and there of ready-dressed cargo of odd lengths to complete the assortment.

(3) The firm may buy a portion of an assortment in the form of ready-dressed cargo, and make up the balance from raw, unworked, loose bristles dressed in its own godown under direct supervision of its own staff or by contract with native bristle dealers.

(4) The firm may buy raw, loose bristles in bulk unsorted and work these by contract with professional bristle dealers who guarantee to supply the labour and to dress according to an agreed standard. If the firm is dealing

with a reliable Chinese bristle contractor, this is possibly the better method than for a firm to dress the raw bristles in its own godown under the direction of its own staff.

Raw cargo for dressing may be secured from local Tientsin dealers or by sending men to the principal collecting centres, such as Mukden, Peking or Paotingfu, or to other interior sources of supply. The firm or the comprador will send out Chinese buyers who arrange the purchases, generally by giving cash advances to the bristle dealers. Some of the Tientsin firms have agents continually resident in the principal bristle centres. These men are always on the outlook for good offerings, and buy a few thousand taels worth of this lot or that lot, as cargo of suitable quality comes to hand. The goods so purchased are then forwarded to the main dressing station, which generally is in Tientsin or its vicinity.

The customary way of buying bristles from regular bristle contractors is to pay the latter a certain amount of advance money, usually 40 to 50 per cent. of the contracted amount. However, many firms, especially those dealing principally in bristles, purchase raw materials direct from interior points through their own agents, and the amount of money required for such interior purchasing depends, of course, upon the extent of the business.

CONDITIONS IN NORTHERN AND CENTRAL PATAGONIA.

The great stretch of territory here designated as northern and central Patagonia comprises the Territories of Rio Negro and Chubut, a part of the Territory of Neuquen, and the greater part of the Territory of Santa Cruz. It contains about 270,000 square miles. The population, however, is not over 100,000, or about one person per 3 square miles, and as most of the inhabitants are found in the coastal towns, the density of population in the interior is less than one person per 10 square miles. With the exception of the valleys along the slopes of the Cordillera, the entire region is a desert sparsely covered with bush and grass, which is unsuitable for cattle raising. Much of the soil is rich; but, owing to the fierce winds and the lack of rainfall, agriculture generally is impracticable. Sheep raising—principally for wool—constitutes the chief industry of this vast region.

It appears from a report by the United States Trade Commissioner at Buenos Aires, that fully half of the total Patagonian population lives in the valleys of the Rio Colorado and the Rio Negro in the extreme north. The northern district has the advantage of railway connection with Bahia Blanca and Buenos Aires, and is, consequently, more developed than the southern part. Considering the size of the territory, railway communications are very inadequate. A branch of the Buenos Aires Great Southern Railway runs from Bahia

Blanca westward through the valleys of the Rio Negro and the Rio Colorado to Zapala, a few miles beyond Neuquen, and a short spur of the Buenos Aires Pacific connects Carmen de Patagones with Bahia Blanca, thus providing northern Patagonia with fair railway facilities. South of these the San Antonio-Bariloche Railway, one of the wide-gauge State railways, penetrates westward 281 miles into the Patagonian sheep lands. Another of the wide-gauge State railways, the Patagonian Railway, extends 124 miles westward from the port of Rivadavia to Colonia Sarmiento, crossing one of the most desolate parts of Patagonia. A metre-gauge line of about 50 miles, owned by an English company, and known as the Central Railway of Chubut, connects the port of Madryn with the lower valley of the River Chubut. Most of these railways run parallel to each other, and up to the present no connecting lines have been built.

Lacking adequate rail communications, Patagonia necessarily must depend to a great extent on shipping, and two lines of coasting steamers maintain three boats each in the service between Patagonian ports and Buenos Aires. The chief ports along the 1,000 miles of coast line, extending from the Rio Negro to the Rio Santa Cruz, are Puerto Madryn, Puerto Deseado, San Antonio, Santa Cruz, and Comodoro Rivadavia. Puerto Madryn has an excellent deep sea harbour, where a few ships put in to discharge cargo for distribution to other Patagonian coast towns; but there is very little intercourse with oversea ports, and most of the business is done with Buenos Aires.

The vegetation of the central and northern Patagonian pampas (high plains) and cañadas (dry valleys) is so sparse that the maximum number of sheep it will support is said to be only a little over 100 per square mile, and much of it will not feed 50 per square mile. It is, therefore, necessary for the small sheep owner to hold at least 50 square miles of land, and the average holding of about 700 ranchmen in this region is officially stated as approximately 65 square miles. The total number of sheep in the district is about 9,000,000, and it is estimated that there are nearly 2,000,000 guanacos, or Patagonian llamas, ranging wild over this area. Sheep intended for meat are driven in flocks either northward to the railway in the valley of the Rio Negro or southward to the meat packing plants in Santa Cruz.

Cattle raising is carried on in the grassy valleys along the slopes of the Patagonian Andes. The young steers, in lots of 1,000, are driven northward along the mountain slopes to the railhead at Zapala, whence they are sent by rail to ranches in the Province of Buenos Aires. The journey to Zapala often takes 30 days. Thirty-four thousand head of cattle, and 83,000 sheep were loaded at Zapala during the summer of 1920.

Agriculture is possible only on a limited scale in this territory. The general difficulty in obtaining sufficient water and the fierce winds and sand storms, which necessitate the construction of costly windbreaks, bar agricultural development on an appreciable scale. Many settlers have been attracted to the upper valley of the Rio Negro, where an extensive irrigation system is under construction, and many fine vineyards, orchards, and apiaries are found near the towns of Allen and General Roca. The cultivable land, however, is limited to a narrow strip of flat valley along the river. Under great difficulties, the Chubut Valley has also been put under irrigation, and some dairying is carried on. A considerable amount of cheese is exported from this district to Buenos Aires. Trelew, a town of about 3,000 population, is the centre of a Welsh colony founded about 50 years ago. It is connected by rail with Puerto Madryn. A colony has also been established by a party of South African Boers a few miles north of Comodoro Rivadavia, and various small mixed colonies are found in the interior and along the eastern slopes of the Andes.

Until a foreign market opens up for Patagonian wool and sheep skins, there is no hope of doing business on an extensive scale with this region, as the price of wool in Buenos Aires covers little more than the freight from the ranches. Business conditions may be said to be fair only about the town of Comodoro Rivadavia, an important factor of this comparative prosperity being, of course, the exploitation of the Government oil fields near that port.

Under normal conditions, there is a market for motor cars, as the cart roads extending all over Patagonia are in fairly good condition, but the prevailing lack of ready money has completely stopped the sale of automobiles in that country. The market for hardware, wire fencing and other ranch needs has declined for the same reason. In normal times also Patagonia imports proportionally large quantities of tinned goods, and a considerable amount of the ordinary luxuries of life. A return to normal imports or better commercial conditions, however, cannot be expected until there is a world market for Patagonian pastoral products.

GENERAL NOTE.

ROAD DEVELOPMENT IN SZECHUEN.—The newly created Bureau of Roads of Szechuen Province, has recently announced its plans to build 2,000 miles of roads within the Province. The first road, writes the United States Vice-Consul at Chungking, will run between Chungking and Chengtu, a distance of 300 miles. The roads will be macadamized and are intended for motor traffic. The work, which was to have started in March last, is under the supervision of a foreign highway construction engineer.

The above list includes all subscriptions received up to July 10th. Further lists will be published in the *Journal* from time to time.

Fellows of the Society are reminded that the amount aimed at by the Council is £50,000, which will enable them to renovate and decorate the House and make it more attractive and convenient.

*The four former lists were published in the *Journals* of December 2nd, 1921, January 13th, February 24th, and May 5th, 1922.

NOTICE.

INDIAN SECTION.

A meeting of the Indian Section Committee was held on Friday, July 7th. Present:—Sir Charles S. Bayley, G.C.I.E., K.C.S.I., in the chair: Sir Charles H. Armstrong, Sir George C. Buchanan, K.C.I.E., M.Inst.C.E., Sir Krishna G. Gupta, K.C.S.I., Sir Charles C. McLeod, Lieut.-Colonel Sir A. Henry McMahon, G.C.M.G., G.C.V.O., K.C.I.E., C.S.I., Mr. Thomas McMorran, Mr. F. Noyce, I.C.S. (Indian Trade Commissioner), Mr. N. C. Sen, O.B.E., and Colonel Sir Charles E. Yate, Bt., C.S.I., C.M.G., M.P., with Mr. G. K. Menzies (Secretary of the Society) and Mr. S. Digby, C.I.E. (Secretary of the Indian and Dominions and Colonies Sections).

PROCEEDINGS OF THE SOCIETY.

TWENTY-THIRD ORDINARY MEETING.

WEDNESDAY, 24TH MAY, 1922.

SIR GEORGE BEILBY, F.R.S., in the chair.

The CHAIRMAN said the reader of the paper had just recovered from a long and very serious illness, and it was a matter of great surprise that he had been able to come to London, against the advice of his friends, to read his paper. He was sure the author would be accorded an extra welcome on that account.

About 21 years ago, Mr Fletcher went to Ireland as Senior Inspector of Technical Education, during Sir Horace Plunkett's regime as Vice-President of the Department of Agriculture and Technical Instruction for Ireland. Subsequently, in 1904, he became Assistant Secretary to the Department in respect of Technical Education, to which latter post he succeeded on Sir Robert Blair's appointment as Education Officer to the L.C.C. Mr. Fletcher had carried on the onerous task of administering technical education in Ireland with patience and tact for the past 20 years, and in that work had won the goodwill of the many diverse bodies with whom

he had had to deal. He was one of the Members of a Committee set up by the Government in 1918 to report on the Co-ordination of Primary, Secondary and Technical Education in Ireland. In 1917 and 1918, he served as a member of the Irish Peat Enquiry Committee, to whose labours he contributed with considerable energy. In many of his papers and lectures dealing with the industrial resources of Ireland, he had given much attention to advancing the claims for the utilisation of peat, with the recovery of by-products for the generation of power on a large scale for use in industry. During 1919, the author acted as a Member of the Irish Water Power Resources Sub-Committee, of which Sir John Purser Griffith was Chairman, and he had thrown himself with great energy into the study of the methods by which the undeveloped industrial resources of Ireland might be made available for the Irish people.

The paper read was :—

THE POWER RESOURCES OF IRELAND.

(Coal, Peat and Water Power).

By GEORGE FLETCHER, F.G.S., M.R.I.A.

It is only during the last few years that the Fuel resources of Ireland have been made the subject of systematic enquiry. I include under the term "Fuel Resources" Water Power, *la Houille Verte*—as such low head falls as we shall deal with, have come to be called in France. It is necessary to qualify this generalisation. Our knowledge of coal reserves has been enriched by the work of the Geological Survey, while in the matter of peat we owe a debt of gratitude to the valuable report of the Bogs Commission which appeared over a century ago (1809-1814). This report however, valuable as it is, was written something like a quarter of a century before Faraday's experimental researches on electromagnetic induction were made and three-quarters of a century before the electrical transmission of energy became a *fait accompli*. The main object of the Commission then was not peat-winning but land-reclamation. The Report suffered the common lot of expert reports. No action was taken on it, and it was well-nigh forgotten.

It needed the stimulus afforded by a great European war to provoke enquiry into the Fuel Resources of Ireland. These had, it is true, been studied by a number of individual enquirers, first among whom must be counted Sir Robert Kane, whose

"Industrial Resources of Ireland" appeared in 1844, but nothing definite or authoritative was available to the public, whose views on the subject of coal, peat and water power, were of necessity extremely vague. There was, however, a widespread demand for authoritative enquiry. The Department of Agriculture and Technical Instruction for Ireland, early in 1917, invited the attention of the Advisory Council of the Department of Scientific and Industrial Research to the question of the utilisation of our peat deposits, and the matter was referred to the Fuel Research Board, with the result that an Irish Committee of Inquiry was appointed with Sir John Griffith as Chairman on July 2nd, and reported on February 26th, 1918, and, after a conference with the Fuel Research Board, rendered a Supplementary Report on July 10th, 1918.

The necessity for collating our knowledge respecting our coal reserves led to the appointment in 1919 of the Irish Coal Industry Committee, while a fuller enquiry was subsequently initiated by Dail Eireann by the appointment of a Commission of Inquiry into the Resources and Industries of Ireland the Power Committee of which have already (1920) issued a *Memoir* on our coal resources, while reports on coal, peat and water power are promised.

In regard to water power, while a large amount of information had been accumulated—mainly as a result of several Royal Commissions and Expert Reports—such information related to navigation and drainage rather than to water power, and though a good deal of information had been obtained through the operations of the Board of Works, there was pressing need for a comprehensive enquiry into our rivers from the point of view of Power, and after the appointment of a Committee to examine and report upon the water power resources of the United Kingdom, the Board of Trade appointed (November 29th, 1918) a Sub-Committee, with Sir John Griffith as Chairman, to report upon the subject so far as it affects Ireland. This Committee reported on December 6th, 1920.

Having thus briefly indicated the main sources of the latest information and opinion on these different but interrelated problems I propose, as far as is possible within the limits of a single paper, to summarise the state of our knowledge and to discuss its bearings from the economic standpoint.

COAL.

In the matter of coal deposits geological processes have treated Ireland unkindly. The great central plain consists of lower carboniferous strata, and this was doubtless covered by coal-bearing strata. The area was then disturbed and folded by the Armorican earth movements, and subsequently subjected to prolonged denudation which stripped off these upper carboniferous coal-bearing strata, leaving only a few isolated deposits, which together occupy an area of somewhat more than 110 square miles. The largest of these forms the Leinster Coalfield (an area of 94 square miles) with the mines of Castle-comer on the west side of the field and the Wolfhill Collieries on the east side, both yielding a good quality of anthracite. To the south-west is the small coal area of Slieve Ardagh also yielding anthracite. The proved reserves of these fields amount to 172 millions of tons, that is, something like nine-tenths of the total proved coal reserves of Ireland. The remaining coal-fields in Co. Tyrone (Coalisland, Dungan-non and Annaghone) at Ballycastle and Lough Allen (Arigna and Slieve-an-Ierin) are semi-bituminous in character. It is possible that additional coal may be found in the Lough Neagh (County Tyrone) area, for the coal measures here dip eastward under the Triassic sandstones—one of the seams here is 9ft. in thickness. The large area of upper carboniferous strata in the counties of Limerick and Clare yield a few occasional seams of anthracite, but for various reasons it has not hitherto been found profitable to develop these measures.

It will be useful to set out the estimates of Irish coal reserves as arrived at by the Irish Coal Industry Committee and the Irish Commission of Inquiry. They are as follows:—

The striking disparity between these two estimates, made within a year or so of each other, calls for explanation—one makes no reference to the Munster Coalfield, which has not been worked for a century, while the other estimates its reserves at 1,570 millions of tons.

The *Memoir* issued by the Commission of Inquiry gives reasons for the inclusion of areas and coals hitherto regarded as uneconomic, arguing that economic conditions are not fixed and unvarying and that a coal which might not be "economic" at one time might become so under other conditions. It was considered better, therefore, to give a full and detailed statement of all reserves. The sliding scale of Economic Conditions could then be adjusted from time to time to this comprehensive statement. In regard to the extensive Munster coalfield it points out that, while it has been neglected in estimating the national coal resources, the *Middle Coal Measures* of this area contain at least six coals, some of which reach thicknesses of 5 and 7 feet, occasionally bulking to double these thicknesses, most of them good quality anthracite. The district is somewhat remote from large industrial centres, offering considerable transport difficulties, and in no part of it has any work been conducted for nearly a century.

This resumé of Ireland's coal resources, compiled on the basis indicated, will be of great value if certain conditions and limitations are understood. It is not possible accurately to forecast economic changes and it is of importance to develop our coal resources as far as possible. A cheerful economist—I think it was Dean Swift—remarked that we should "burn everything English except their coal," and it is clearly

	Commission of Inquiry.	Coal Industry Committee.	
		Actual Reserves.	Probable Reserves.
	Tons.	Metric Tons.	Metric Tons
Leinster Coalfield ..	299,000,000	156,730,000	—
Slieve Ardagh Coalfield ..	40,000,000	15,080,000	—
Munster Coalfield ..	1,570,000,000	—	—
Connacht Coalfield ..	29,000,000	8,696,000	—
Ballycastle Coalfield ..	49,000,000	—	13,720,000
Coalisland Coalfield ..	40,000,000	—	31,210,000
Annaghone Coalfield ..	17,000,000	—	3,000,000
Total	2,044,000,000	180,506,000	47,930,000

undesirable that Irish industries should be at the mercy of a fuel supply wholly outside their control. It is this which renders the question of power resources a vital one for Ireland. It is a significant fact that Ireland does not raise more than one-fiftieth of the coal consumed in Ireland and it does not appear that under existing economic conditions she can replace her coal imports by native coal alone. It does not follow that she need continue to import $4\frac{1}{2}$ million tons of English coal. It appears highly probable, indeed, that she can with great advantage to herself replace the greater portion of this by increasing the output of her own mines, and by utilising more fully her splendid peat deposits and water power.

It is, however, important to remember that under existing economic conditions, Irish coal must be raised in competition with imported coal and in competition with other fuels. It seems very probable that long before the existing Irish mines are exhausted Irish peat will have proved itself a serious economic rival. It must not be forgotten that the tendency is for the cost of winning coal to increase progressively as the depth and distance of working faces from shafts increase. This disadvantage, common to all coal-mining operations, is aggravated in Ireland by the thinness of the seams and the consequent necessity to remove great quantities of waste material in order to win the coal. This accounts in large measure for the fact that while in Great Britain the annual output per underground worker is 294 tons, it is, in Ireland, only 149 tons. As the miner is paid by the amount raised by him the wages of the Irish worker are less than those of his British *confrère*. To these disabilities must be added that of inadequate transport. Prior to the war the existing collieries were not on or even near a railway. During the war a railway 10 miles in length has been built connecting the Castlecomer Collieries with the existing line at Dunmore, near Kilkenny. Another, also 10 miles in length, was built to connect the Colliery at Wolfhill with Athy, while a short line now connects Arigna with the mines. This improved transport, together with improved methods of winning should lead to an increased output for home consumption. The annual output of Irish coal may be taken as about 90,000 tons or about one-fiftieth of the amount

imported—4,500,000 tons. The amount of coal raised in Ireland in the year 1854 was 148,750 tons, and the output has declined pretty consistently ever since. The Irish Coal Industry Committee expressed the view that "with reasonable transport and housing facilities" the output might be increased to 500,000 tons. While every effort should be made to increase the output and to increase the efficiency of winning the coal, it will be evident that, in view of the facts I have stated, peculiar economic importance attaches to our other fuel resources. Before dealing with these it will be convenient to state Ireland's annual consumption of fuel. It is as follows:—

	Tons.
Coal (imported) ..	4,500,000
Coal (mined in Ireland) ..	90,000
Peat (won in Ireland) ..	7,000,000

Taking the Peat as having a calorific value half that of coal our total fuel consumption may be taken to equal approximately 8,090,000 tons of coal. Little more than a quarter of the imported coal gets inland beyond the large coastal towns. Somewhat over two million tons is used for domestic purposes and a little less than $1\frac{1}{2}$ million tons is used for Industrial purposes, the remainder being consumed by Railways and by Gas and Electricity works. The domestic fuel of the great mass of the people is hand-cut turf or peat.

PEAT.

In spite of the fact that some seven millions of tons of air-dried peat are consumed annually by domestic hearths in Ireland, our reserves of this fuel are enormous. It is estimated that our bogs contain no less a quantity of peat than 4,000 million tons—reckoned as "air dried" (25% moisture) an amount sufficient to meet our present fuel requirements for all purposes for something like 200 years.

It will be convenient to distinguish between two principal types of bog, viz.: (1) the scattered mountain bogs, the cutting of which with the "slane" yields the main source of fuel to the rural population of Ireland; probably a million and a half of the people depend solely on peat for domestic uses, and (2) the great flat bogs which overlie so much of the great central plain. These great tracts of flat and deep bogs contain nearly 2,000 million tons of peat calculated as anhydrous.

Nearly three-fourths of this lies within a "central belt" bounded on the north by a line joining Howth with Sligo and on the south by a line joining Wicklow with Galway. While the mountain bogs are being cut away and used as domestic fuel, the large flat bogs have scarcely been utilised, and though their margins have been cut for domestic purposes their outline has scarcely been modified since the survey of the Bogs Commission over a century ago. Their utilisation presents a most interesting economic problem which, until the last year or two, has received far less attention than it deserves. Of speculation and individual adventure, with expenditure of large sums of money, there has been plenty, and many distressing failures might have been avoided if the truth of the First Law of Thermodynamics and certain economic principles had been recognised and applied. The chemical and physical properties of peat offer a perplexing problem to those who seek to utilise this great natural resource and the problem will only be solved by scientific experiment and a recognition of economic principles. Permit me briefly to describe these properties in so far as they are relevant to economic development.

The salient fact about peat as it occurs in nature is its extreme and ineradicable wetness. An undrained bog may be assumed to contain from 90 to 95 per cent. of water. Efficient draining may reduce this to between 91 and 88 per cent. Thus, in a bog containing 90 per cent. of water, the small farmer, in order to win his year's supply of turf, which may be taken to average 25 tons when air-dried to 25 per cent. moisture (spoken of hereafter simply as "air-dried") must cut and spread no less than 188 tons of raw peat. Indeed, if allowance be made for losses in dust and "smalls" necessarily left behind on the bog, the amount to be raised must be over 200 tons of raw peat. In spite of the labour involved, this fuel is of enormous value to the population of the south and west. In the Province of Connaught, for example, the annual consumption of coal per head of population amounts to less than one-fifth of a ton. It is necessary to conserve this fuel for the use of rural-dwellers. In certain densely populated districts occupied by small land owners, it is possible that, owing to the exhaustion of the small local turbaries, it may be

necessary to migrate families unless provision can be made for the supply of fuel from a distance. This consideration brings me to the second defect of peat as a fuel. The average calorific value of "air dried" peat lies between 6,000 and 7,000 B.Th.U. per pound. That of coal as supplied in Dublin is from 11,000 to 12,000 B.Th.U. per pound. Taking the mean of these figures, the calorific ratio of coal to peat will be as 1.77 to 1 or, put differently, 1.77 tons of peat will be required to give the same amount of heat as one ton of coal. This quantity of peat will, when loaded, occupy from $3\frac{1}{2}$ to $5\frac{1}{2}$ times the space occupied by one ton of coal. This bulkiness of peat combined with its friability offers transport difficulties which militate against its use at a distance from the bog, though it is necessarily carried by road and canal. About 6,500 tons of peat is brought yearly from the Bog of Allen by the Grand Canal to Dublin, and used for domestic purposes, while a good deal is carried along the coast of Connemara in the small sailing boats known as "hookers." For many years past efforts have been made to overcome these defects. Attempts were made to express the water by compressing the peat, but the manner in which the water is retained by the vegetable fibres renders this impracticable. The maximum effect produced by pressure is to reduce the water content from 90 per cent. to 70 per cent. It was then sought to break up the fibre, in some cases by maceration, in others by treating the peat with super-heated steam or high tension electricity or by admixture with some mineral substance such as lime. The fibre can, no doubt, be broken up, and the expulsion of the water by pressure thus rendered possible, but the Irish Peat Enquiry Committee reported that, so far as they knew, "no successful process exists for eliminating the excess water contained in peat other than natural air-drying."

It would be outside the scope of this lecture to deal with these various experiments, but I must refer to the very interesting work recently done in maceration at Turraun, because of the practical bearing of the results obtained. The process of maceration is accomplished by feeding raw peat into a machine which has usually an arrangement of fixed and rotating knives arranged spirally in such a manner that the vegetable fibre in the peat is cut or torn and the whole mixed up and pressed out

in a continuous band through a mouth-piece of suitable shape. This pulp-like band of macerated peat is cut into sods and spread on the drying ground. The effects of maceration may be summarised as follows:—

(1) Since the light spongy peat from the surface and the more dense black peat from the bottom of the bog can be thoroughly mixed a more uniform product is secured.

(2) The macerated peat dries much more quickly than non-macerated peat, and in a few days a surface film is produced which in a large measure protects the sod from rain.

(3) The resulting sods are much more compact, having a higher density than those resulting from unmacerated peat. While a ton of unmacerated slane-cut peat fuel occupies approximately 140 cubic feet, a ton of the macerated product occupies only 100 cubic feet—instead of occupying $5\frac{1}{2}$ times the space which would be occupied by its calorific equivalent of coal it only occupies four times this space.

(4) The improved density and texture of macerated peat enables it to be "footed" and harvested with slight loss from dust and smalls, its transit qualities are enormously improved and it is rendered much more suitable for producer plant and gas retorts. Its use in the latter is under experiment by the Fuel Research Board at their Research Station at East Greenwich, and a report on "The Carbonisation of Peat in Vertical Gas Retorts" has been issued.

There is no reason to doubt that maceration will play an important part in peat utilisation in Ireland. It will secure a fuel supply to those districts where the small local bogs are exhausted. It may also find an extended use for industrial purposes, but it is impossible to avoid the conclusion that, for such purposes, a fuel of this character should, *in situ*, be converted into energy which might be either transmitted electrically to industrial centres or employed for electro-chemical industries in the neighbourhood.

The Irish Peat Inquiry Committee made a series of recommendations in this sense. Their first task was to arrive at a rating for peat. Working on pre-war labour rates they found that in the case of the bog at Ticknevin, Co. Kildare, the actual cost of winning and "clamping" on the bog was 2.76 shillings per ton air-dried. The total cost of winning and stacking the peat on the canal bank $1\frac{1}{2}$ miles away was 5.96

shillings per ton. This would enable peat to compete with coal at this point. The calculations were based upon a wage of 12s. per week of 72 hours. It is hardly necessary to point out that a great change has taken place, and that it is highly improbable that such conditions will recur. There would be little advantage under present conditions in endeavouring to bring these ratings up to date.

The Committee recommended the State purchase of a large bog and the initiation of experiments on a large scale, including systematic drainage and reclamation of the bog so as to fit it for cultivation and ultimate use for peat-winning. 'Different types of peat-winning machines were to be employed for comparative tests'. It was proposed to instal gas producers in which peat was to be used, and the by-products recovered, the power to be employed in producing electric power for distribution, etc.

The Fuel Research Board, after a careful consideration of the report, held a conference with the Committee, as a result of which it submitted a supplementary report dated July 10th, 1918. This report was accompanied by estimates and involved a less extensive scheme than that which had been proposed, but adequate to the demand for experimental enquiry. The Fuel Research Board concurred generally in these recommendations, remarking that "The Board are of opinion that if satisfactory arrangements can be made for the purchase and holding of a selected bog area, and for the management of an agricultural colony on that area, then the (above) expenditure on the establishment and running of an experimental station would be justified; for the results obtained ought once for all to clear away the uncertainty which has hitherto prevailed as to the economic possibilities of the bogs of Ireland." It should be pointed out that the proposed experiments involved machine digging with air-drying. The operations concerned with the latter are seasonal and hence it becomes necessary to find for the families engaged in the work some auxiliary employment, and this it was proposed to find in the reclamation and cultivation of the bog surface and also of the cut-away surface. Such an association of the agricultural and fuel industries is common in Canada, the United States and European countries, and in many

places in Ireland excellent crops are to be found growing both on the virgin-bog and on the cut-away bog.

The recommendations of the Committee have not yet been carried out. It is not my purpose to discuss the reasons for this, but so great is the economic importance of the matter, and so widely is this recognised, as is shown by the creation of a Commission to enquire further into it (among other cognate questions) that I feel satisfied it will shortly be dealt with effectively by an Irish Government. It must not be supposed, however, that no work had been done on the subject subsequent to the issue of the Committee's reports. The Fuel Research Board, in addition to the work carried out in their experimental station at East Greenwich, have been collecting information from abroad, and my friend, Professor Purcell, of University College, Dublin, has, in connexion with the Board, extended the valuable work he did as Secretary of the Irish Peat Inquiry Committee. His lecture on "The Peat Resources of Ireland," is a valuable contribution to the subject, while his colleague, Professor Ryan, has laid us under an obligation by his translation of Hausding's *Handbuch der Torfgewinnung und Torfverwertung*. Both have been published by the Fuel Research Board.

WATER POWER.

The causes which led to the creation of a Water Power Resources Committee by the Board of Trade led to the appointment of an Irish Sub-Committee on June 20th, 1918. The Sub-Committee were fortunate in having as its Chairman Sir John Griffith, who had also been Chairman of the Irish Peat Inquiry Committee, and whose long engineering experience and mature judgment were an invaluable asset.

It will not be useless to enquire at this point the reasons for the lamentable delay in developing the power available in the water courses of these Islands. This development has lagged long years after the satisfactory demonstration of the engineering and economic success of water power schemes in Europe and elsewhere. Our great resources of coal have, doubtless, been an important factor, and water power will still have to compete with this rival—at all events until public opinion has been awakened to the unwisdom and the danger to our industrial status of allowing to run

to waste a perennial source of energy, while lavishly expending at an ever-increasing rate the fuel capital of our coal fields. But this excuse—the availability of cheap coal—cannot be urged as adequate in the case of Ireland, which for many years has imported large quantities of coal from Britain.

As far back as 80 years ago water power was largely used in Ireland, and disused mills with derelict water wheels—some of considerable size—are thickly scattered over our river valleys. With the development of steam plant and railway development, an inevitable change took place. It became necessary for industries to take advantage of the new transport facilities, and of the superior labour supply available in populous centres. The water power was precarious, subject to occasional droughts and floods, and, naturally, gave place to the assured continuity of steam power, except in the relatively few instances where turbines were installed, and the other conditions were not unfavourable to the use of water power.

The electrical transmission of energy has changed all this, and it is now seen that the utilisation of our natural stores of energy, whether water power or coal or peat, is not altogether a question for the individual, and that the State must take a hand in the regulation and control of these resources.

There has, hitherto, been considerable vagueness as to the approximate amount of water power which might be developed from the rivers of Ireland. The conformation of the country with its extensive and low-lying central plain and coastal mountains, and the absence of any but moderate falls, gave rise to the belief that there was no power worth speaking of. On the other hand, estimates were made which must be regarded as extravagant. Sir Robert Kane, in his "Industrial Resources of Ireland," made an estimate based on rainfall (which he took to be 36 inches per annum) with an allowance for evaporation losses, and an average elevation for the country of 387 feet. Assuming complete regulation by storage throughout the year, he estimated that the available power amounted to 1,275,000 water horse power continuous. If we revise this estimate in the light of more recent data as to rainfall and evaporation, we should have to raise his figures to nearly three millions. Such an estimate may be fairly compared to

that of our coal resources which includes thin and inferior coals, which could not be developed under existing economic conditions, for *complete regulation* by storage of all our water courses is impossible of attainment.

The Water Power Resources of Ireland Sub-Committee investigated the power available on four of the larger Irish rivers, and using this as a basis for their calculations, arrived at the conclusion that 500,000 W.H.P. can be continuously and economically developed for the whole country. Using storage, this is equivalent to 1,750,000 W.H.P. for 8 hours per day for 6 days per week. Want of funds prevented the Sub-Committee from making full investigation of other Irish rivers, but they are satisfied from the data obtained in regard to the Shannon, Erne, Bann and Liffey, that the foregoing estimate is reasonable. They realised, nevertheless, the pressing need for the collection of additional data, and recommend that the systematic gauging of the rivers should be at once undertaken. The rainfall records are also inadequate. Nearly all the existing rainfall stations in Ireland are in low-lying districts, and there is great need of records for elevations of 500 feet and over, and also for determinations of evaporation losses. These were made the subject of recommendations. While systematic gauging of rivers is obviously important, I venture to urge the value of accurate rainfall statistics and data as to evaporation losses under meteorological conditions which exist in Ireland. Such data with the careful study of the geological structure of a catchment area, with a view to determining what underground losses there might be from the area, would enable reasonable estimates of run-off to be made. I am indebted to the Geological Survey of Ireland for the excellent maps indicating the geological structure of the river-basins referred to.

The Committee obtained reports on the Shannon, Erne, Bann and Liffey from the unmentioned engineers:—

Shannon—Mr. Theodore Stevens.

Erne—Mr. Theodore Stevens.

Bann (Lower)—Mr. Charles S. Meik.

Liffey—Mr. J. W. Griffith, in collaboration with Prof. H. H. Jeffcott.

The first three of these rivers have, on many occasions, been the subject of enquiry, and numerous commissions and expert reports have dealt with the problems which

at the time were paramount, viz., navigation and drainage. These are set out briefly in the report of the Sub-Committee. Any schemes for the development of water power on our rivers must respect these important interests, as well as that of our valuable inland fisheries, and the difficulty of the problem of reconciling them has, doubtless, been one of the causes of the failure to utilise the rivers for power purposes. Previous schemes for the Shannon and the Erne have involved the diversion of the river—or such part of its water as the guardians of these interests would allow the water power engineer to take—into a head race or canal, and to a point selected for a power station. Such canals are expensive to construct, and the diversion of the water from the river course, especially where the length of the canal is considerable, raises many difficulties. The Sub-Committee considered, therefore, a scheme of development which would not involve diverting the river from its bed. Instead of constructing a long and expensive head race, they suggested, instead of the single power station, three or four smaller ones, electrically connected. At first sight such an arrangement would seem to be uneconomical. Investigation shows that this is not the case. Although several barrages are required instead of one, the great cost of a long head race is saved. The necessity for compensation water is avoided, and interference with fishing interests is reduced to a minimum. A marked advantage is that the scheme can be developed in stages as the demand for power develops. It was with these advantages in mind that the Sub-Committee submitted the suggestion to Mr. Theodore Stevens who, after careful consideration and investigation, submitted schemes both for the Shannon and the Erne, based on this principle. These schemes not only secured a far larger output of power, but secured it at a much lower cost per horse power in each case.

The schemes for all four rivers involve storage. In the case of the three larger ones, natural reservoirs exist in the loughs which lie on their courses and the level of which it is proposed to vary. In the case of the Liffey, it is proposed to construct a barrage across the gorge at Poulaphouca, and thus create an artificial lake. The flooding of 4,000 acres will raise the water level in this storage reservoir to the 600 feet contour line, and this will permit of a

complete regulation of the flow. The Sub-Committee attach great importance to the provision of adequate storage. The topographical and meteorological features of Ireland render storage desirable, not only with a view to fully developing water power for industrial purposes, but also of regulating river flow, and thus mitigating on the one hand the effects of drought, and, on the other, preventing the floods which effect such damage along the low-lying banks of many of our rivers. From the point of view of power production, the conservation by storage of the excess winter flow for use during the summer months is analogous to the part played by the summer melting of glaciers in regions where they enjoy the advantages of a *regime mixte*. There seems a tendency to regard storage as a *pis aller*. It is, in fact, of the essence of these schemes.

The limit of time set to a lecture will not permit me to deal with these rivers in detail, but I have compiled from the Report the estimates of power and cost of the schemes which are set out in the following table:—

	Electrical Horse Power		Cost.			
	Installed.	Average continuous.	Total.	Per Horse Power Installed	Per Horse Power continuous.	
			£	£	£	
Shannon	65,900	52,500	2,834,000	43	54	Four stations between Killaloe and Limerick.
Erne	71,300	45,500	2,060,000	29	46	Four stations between Belleek and the sea.
Bann (Upper) ..	(a)					
	13,424	5,369	759,200	56.5	141.3	With load factor of .4
		5,369	360,800	—	67.2	With load factor of 1
	(b)					
	11,932	4,772	748,500	62.75	156.8	With load factor of .4
		4,772	340,800	—	71.4	With load factor of 1
Liffey	29,600	8,300	920,000	31	111	Six stations.

The proposed scheme for the Liffey is of great interest, because of its neighbourhood to the great industrial centre of Dublin. It is estimated that it would be possible to deliver power at low tension in Dublin amounting to 48 million units in a mean year, and would cost about $\frac{1}{2}$ d. per unit. The total output of all the electric power stations in the Dublin district amounts to nearly 31 million units. It seems probable

that the Liffey and the Bann will be the first Irish rivers to be developed.

The mountain lakes of Donegal, Connemara, Kerry and Wicklow offer great possibilities, and it is estimated that an aggregate of at least 40,000 E.H.P. continuous might be developed from them. Some of these lakes could yield 500 E.H.P., the average being about 175 E.H.P. In many cases, at all events, these would be of great value to local industry, for it would seem that the capital cost of development would be low, in some cases as low as £30 per E.H.P.

If we accept the careful estimate of the Irish Sub-Committee that there are half a million water horse power available continuously in Ireland, we may arrive at an approximate idea of its money value. It does not seem likely that the estimate of coal consumption in existing steam plant, which was taken as averaging 5 lbs. per horse power hour, is over the mark. Taking this as a basis, our undeveloped water power is equivalent to 7,500,000 tons of coal,

or, taking the money value of power at, say, 1d. per B.O.T. unit, our half million W.H.P. has a value of about £10,000,000 per annum. Moreover, supply of power for industrial purposes, at the rate of .1d. per unit, would confer enormous advantages on our industries. These facts are not yet fully appreciated. Ireland, it is urged, is an agricultural country, and the suggestion is that it cannot be an industrial country.

A suggestion of water power development, and the provision of cheap power for industries, is met by the exasperating retort that there are no industries to employ the power. The lack of cheap power has been often urged, with good reason, as a reason for our industrial backwardness.

So far as Agriculture is concerned, it is much to be desired that Ireland should become more agricultural—using the word in its truer sense. The decline of tillage in Ireland has been almost continuous since the middle of last century, and while the number of cattle has correspondingly increased the population of the country has declined with hideous regularity until it is now about half what it was in 1841. Increased cultivation and resuscitated industries would repair this. Increased cultivation will be secured by diminishing the cost of production and the supply of cheap electrical power for farming operations will aid in bringing this about. Similarly, the supply of cheap power to the country towns will not only enable existing industries to compete on fairer terms with their rivals, but will, beyond question, lead to the establishment of new industries. I need scarcely say that this argument is not exclusively applicable to Ireland, but, for reasons which I cannot here discuss, the application of our natural power resources to industrial development has been shamefully tardy, and there is danger that if further delayed we may lose much of its economic value. This tendency in such matters to wait for an almost mathematical demonstration of success before adventuring is a national failing. On this point I hope you will allow me to make a brief digression. Twenty-one years ago I was visiting the works of Messrs. Escher Wyss, at Zurich. They informed me that they had just been supplying plant for a hydro-electric station near Grenoble. This station was the first to be installed in this district and was for a new company, *The Société hydro-électrique de Fure et Morge*, and there were points of interest about it that seized my attention. Grenoble, a town of some 80,000 inhabitants, is the principal town of the Department of the Isère. Its principal industry is glove-making. The Department of the Isère is agricultural, but has now become an important industrial region. It has considerable deposits of coal, lignite and iron. Some 12½ miles down the Isère,

north-west from Grenoble, along the valleys of the Fure and the Morge, are scattered a number of industries—paper-making, silk-weaving, tool and saw mills. About 21 years ago the manufacturers in these valleys sought to employ electric energy as a motive power. They agreed to co-operate. *The Société hydro-électrique de Fure et Morge* was formed in order to organise the supply. The manufacturers referred to became members of the syndicate and undertook before the station was erected to use 3,000 horse-power. It was a condition that, at the expiration of thirty years, the syndicate should become the proprietors of the whole installation and the capital of the *Société hydro-électrique*, should be amortised and the Company itself cease to be. A suitable power site was found at Champ on the Drac, about 16 kilometres south of Grenoble. "The scheme was carried to a successful issue and exhibited many points of interest as a pioneering effort. I should not be justified in describing the station, but it is interesting to note that the voltage employed (26,000) was the highest used in France at that date. Also, that reinforced concrete was used for the pipe line over a section 2,100 metres in length. This, I have said, was a pioneering effort, and it was quickly followed by others. The Grenobloises did not wait for an industry to be established before supplying cheap power—they supplied the power and this begot the industry. I visited Grenoble last year and found it a hive of industry. There were by March 1st, 1916, in the Department of the Isère, no fewer than 21 companies with 31 power installations, having a total output of 170,330 horse power in addition to a large number of installations of less than 800 h.p. About half the power generated is used locally for electro-metallurgical and electro-chemical industries. On this date, seven other generating stations—for a normal output of over 47,000 h.p.—were under construction and during the darkest days of the war schemes for commercial and industrial construction formed the subject of lectures and propaganda in which the Grenoble Chamber of Commerce played a leading part.

The bearing of this brief recital on our own problems does not need comment.

In conclusion, I should like to emphasise the importance of establishing an Authority to take control of our water resources.

The principal function of such an Authority would be to allocate water as between the different interests—power, navigation, fisheries, potable supplies, etc. There should also be established a National Service having for its object the development of our water power resources. There are strong arguments in favour of such a service taking over control of sources of power supply. Mr. Laurence Kettle, the City Electrical Engineer of Dublin—who was a member of the Irish Sub-Committee on Water Power—has in an article on “Ireland’s Sources of Power Supply” in the current number of “Studies,” boldly advocated the State taking possession of the sources of power supply, and is of opinion that this will be a cheap and simple matter as there are few vested interests to be bought out. It does not seem to be useful to discuss this large question at the present moment, but it is certain that, in order to secure efficiency and economy in the utilisation of our power supplies, the State must undertake the control, conservation and development of these, and that the question is one which should be tackled at once.

DISCUSSION.

DR J. A. HARKER, F.R.S., said the author, in his very interesting paper, had referred to the many attempts that had been made by inventors and adventurers of all kinds to deal with the problem of the drying of peat, and had mentioned that those people had been, up against the first law of thermo-dynamics. Personally, he would have expressed that statement a little differently by saying that they were battling against a constant of nature, namely, the high value of the latent heat of steam. The fact that the latent heat of steam, which expressed in centigrade units is 539, was so high, was a most convenient thing for the steam engineer who was thinking of turbines and machinery of that kind, but it was a serious disadvantage for the man who wished to get rid of water from peat. The economics of the question of the utilisation of peat largely lay in the fact that the substance which had to be got rid of out of the peat contained the largest amount of latent heat of any material. If it had been as low as alcohol, it would have been a very simple problem indeed. It had been pointed out by the Canadian Department of Mines, in one of their admirable periodicals, that to dry peat containing about 85 per cent. of moisture required the expenditure of the whole calorific value of the resulting products. Supposing that with a ton of theoretically dry

material, whose calorific value was somewhere between 9,000 and 10,000 B.T.U.’s per pound, an endeavour was made to start a peat factory with the object of drying some wet material. If roughly seven tons of the material to which the author referred containing 90 per cent of peat were used, there would then be only enough energy in one ton of dry stuff to get rid of the water, and, therefore, the whole process was somewhat like a serpent swallowing its own tail. There was so little margin that it was impossible to be sure whether the economics of the business were sound or not. That was also on the assumption that an absolutely perfect machine was used which got rid of the steam at a moderately low temperature, the supposition being made that an evaporising process with warm gases was being used, and that the gases were being taken away from the machine at something like 600°F., no account whatever being taken of the inefficiency due to radiation losses.

Some time ago it was part of his duty to visit the works of the Wet Carbonising Company, which was one of the largest undertakings, formed with the object of drying peat on a big scale. He remembered on that occasion being told that if the scheme worked in the most successful manner, it was only hoped to get between 5 and 10 per cent. of the whole output of briquettes left over as the ultimate result after the peat had been treated. The company claimed that the process, which was a briquetting and nitrogen recovery process, would give blocks probably harder and of a higher calorific value than the macerated peat shown that evening, although these briquettes did not differ greatly in appearance and properties from the briquettes obtained from powdered coal in South Wales. The briquettes, however, only consisted of something like 5 per cent. to 10 per cent. of the whole material treated. Roughly, 90 per cent. of what was made was consumed in the process, in order to supply fuel for one or other of the requirements—fuel-gas or power to drive the crushing machines, the squeezing presses, and various other machines used in the process. The author had referred several times to Irish dried peat as containing 25 per cent. of moisture. The speaker would be very glad to hear that he was wrong, and to learn that the author possessed evidence that 25 per cent. was the average figure. He thought he was right in saying that in Italy, where the atmospheric conditions were probably a great deal more favourable for air-drying than in Ireland, the statistics showed that from 30 per cent. to 33 per cent. was the figure obtained with moderate air-drying. If 25 per cent. was obtained in Ireland, he thought the author was to be congratulated, particularly in view of the fact that the atmosphere was undoubtedly a great deal damper in Ireland than in Italy.

In the report of the Nitrogen Products Committee, published two years ago, reference was made to an important Irish peat scheme in the North of Ireland, in which the promoters proposed to gasify part of the peat. They produced electricity with part of it; recovered the nitrogen as ammonium sulphate, and the material on which they were supposed to be working was said to contain an average of about 2 per cent. of nitrogen. It was proposed, in the first place, to air-dry the peat and then further to reduce the original water content, which was of course, high, varying from 85 per cent. to 92 per cent., by means of hot gases. By that method it was proposed to dry a portion of the material until it contained a water content of only 15 per cent., and then use it as peat fuel to generate electricity on a considerable scale. By far the most important source of revenue from the original scheme was to be obtained from the sale of the sulphate of ammonia. Of the many products derived from peat, sulphate of ammonia was incomparably the most important as a commercial asset. It was far more important than the tar oils and the other by-products. The available nitrogen contents of the particular class of peat that was to be worked was of first importance, because if a good deal of sulphate of ammonia could be obtained from it that would prove to be a very valuable asset. If the peat contained little nitrogen, say, only 1 per cent., it was nearly as costly to put up the plant to recover that 1 per cent. as it was to recover a reasonable proportion from the 2 per cent. or 3 per cent. material existing in Norfolk. He thought it was well worth drawing the attention of those who were trying to develop Irish peat bogs to the fact that sulphate of ammonia obtainable from peat was one of the chief economic factors in the whole situation.

PROFESSOR H. H. JEFFCOTT thought that the subject of the paper had been well-chosen in that both heat and water power were contained in it, as he was of opinion that these two questions had a bearing one upon the other. After all, power was the real unit and a fundamental condition of the age in which we lived. Present day civilisation depended on power to a greater extent than many people realised. He therefore thought that Mr. Fletcher had done well in the selection of the title of his paper and in giving an account chiefly of these two sources of energy. A good deal had lately been heard about the depression that existed in industrial life, but he hoped they would have sufficient enterprise and courage to go ahead in spite of difficulties and make successful development of the natural resources that had been proved to be available. He was sorry he was unable to say very much from the point of view of peat, but he had been associated with the problem of water power in Ireland and he knew that this resource was of very great value. There was

economically available in the water resources of Ireland about seven times the amount of power that was at present being consumed for industrial purposes, and it could be obtained much more cheaply than power developed from coal in the locality. The cost of water power might be from one-fifth to one-tenth of that of power from coal in Ireland. Very great results were to be expected from water power in that country if the subject was handled in a sound way. The author had outlined in his paper, the systems that had been proposed for dealing with four of the principal Irish rivers. He hoped that when the works referred to were completed they would be examples for a long time of the comprehensive method by which rivers of the kind should be dealt with. It was of great importance that the whole river should be developed in such a way as to secure the greatest possible economic benefit, not only in water power but also having regard to navigation, fishery, drainage, and other interests in the river. He hoped that such comprehensive treatment would always be insisted upon.

DR. J. F. CROWLEY said the Canadian Government were the first Government to appoint a Power Commission, dealing with problems of the character referred to in the paper, as distinct from Commissions dealing with electricity obtained from water, peat, coal or other possible sources of power. Turning to the headings under which the author had dealt with the subject, the first being coal, the author had pointed out that for domestic purposes in Ireland some 3,000,000 tons of coal per annum were used, while on the other hand for industrial purposes only $1\frac{1}{2}$ million tons of coal were employed. While he was acting as Irish representative on the Electricity Supply Committee of the Board of Trade, he obtained some statistics with regard to the consumption of coal for various purposes in Ireland, and found that approximately $4\frac{1}{2}$ million tons were used by the railways. That meant that an extraordinarily small quantity of coal was used for power purposes in the whole of Ireland, in fact on investigation it was found that approximately 300,000 horse power was the sum total of the horse power used for industry in that country as compared with over 13,000,000 horse power in England. That showed what an appallingly backward position industrial Ireland occupied. The author had pointed out that the equivalent of $3\frac{1}{2}$ million tons of coal was raised annually in peat from Ireland. He was very glad that Dr. Harker had spoken so definitely on the subject of peat, because he very much feared that with the development of industry in Ireland, undue attention might be paid to developments that would not pay and which were unsound economically. The author had drawn attention to the fact that it was necessary to handle 200 tons of peat in order to obtain 25 tons of peat that could be dealt with, and that $1\frac{1}{2}$ tons of

the latter article was equivalent to one ton of coal. The economic position in regard to peat was extremely difficult, and he advised those bodies in Ireland which would have the development of the power resources of the country under their control to move very slowly and very cautiously with regard to any expenditure on peat from the point of view of power production. Personally he was very definitely of the opinion that peat should follow after water in the development of the resources of the country. Some water resources had been thoroughly investigated, and from the point of view of present day power economies they were a first class proposition to develop in many cases, particularly where the power existed and the demand for it. The author had shown some figures illustrating that the cost per horse power was extremely low. It was only fair to point out, however, that those particular schemes would have to wait for some little while because they were very remote, even from an electrical transmission point of view, from centres of industry. The river Bann, however, was within 30 miles of Belfast and also within 15 miles of three other centres of industry, while the Liffey Power Station was within a somewhat similar distance of the city of Dublin. Therefore, he thought the cost per horse power of developing the Bann and the Liffey did not compare favourably with the cost on the Erne and the Shannon. With regard to peat, the author pointed out that, taking 12/- a week as the cost of labour for a week of 72 hours, the cost of a ton of air-dried peat was 6/-. that ton of peat comparing in the ratio of $1\frac{1}{2}$ to 1 with a ton of coal. Generally speaking the power situation in Ireland might be summarised as follows:— that from the point of view of power development on anything like a large scale there were perhaps four or five water power schemes that would bear development immediately the power needs justified them, and in two cases the power needs justified them at the present moment. Once those water schemes were developed, coal stations were the only practicable undertakings on a large scale. Coal, apart from water, was the only possible source of cheap power. There was no doubt, however, that the Irish Government should carefully watch the developments that took place in connection with peat in Sweden, Denmark and Canada and carry out experiments on the subject. Speaking not from the point of view of an enthusiast of peat but from the point of view of a power engineer, in his opinion power would be developed firstly from water and secondly from coal. Turning for a moment to what was practical politics, the question arose as to what steps should be taken to develop power possibilities immediately. The author had suggested that the water companies should be taken over by the State, and that a body should be appointed to deal with water and its allocation. When the Irish

Water Resources Committee sat and considered what report it should make to the Board of Trade, it must be borne in mind that at the time the country was under the shadow of changing political conditions. It was necessary to remember that, because it was possible that the Report would otherwise have taken into consideration the proper Irish Ministry to deal with the subject. When they were acting under the shadow of changing political conditions their ideas as to the administration and executive functions of the bodies proposed were certainly governed to a certain extent by those conditions. He ventured to suggest that rather than appoint either a Water Commission or a Peat Commission or even an Electricity Commission on the lines adopted in this country it would be wise for those dealing with those matters in Ireland to consider whether an over-reaching power Commission, with power to deal with every possible source of power with a view to conserving the natural resources of the country, would not be a better body to appoint. He spoke loyally as a member of the Committee which made the Report, which was quite soundly made on the views that could be taken at that particular period, but conditions had changed. Viewing things in a broad way, he thought a Power Commission of the nature he had suggested would be a better body to appoint than either a Water Commission, an Electricity Commission, or a Peat Commission. Any body which was appointed should have administrative and executive functions with powers of initiation, because if there was one thing more than another in which Irish conditions differed from the more established conditions in this country it was that the initiative had been expected to come, in the conditions that had existed in the last hundred years, from outside rather than inside. For some time to come that expectation would continue, and it was desirable the Government should realise that that expectation existed and provide the initiative itself.

MR. THEODORE STEVENS, in dealing with a point referred to by the previous speaker, said that personally he would desire a Commission to be appointed to deal not only with power but industry. One thing for which he wished to apologise in his report on the water power of Ireland was that he worked out the cost assuming a 42 per cent. load factor, but it was necessary first of all to establish industries to utilise the power before such a load-factor could be obtained. Between 20,000 and 30,000 tons of carbide were imported into this country per annum, and a great amount of cyanamide, and he saw no reason why Ireland should not make all the carbide and cyanamide that were used in the British Islands. There was sufficient power for the purpose in Ireland, and that would have the effect of developing the load factor obtained from the use of water power. He quite agreed

that the Liffey was the first river that should be developed if Dublin was being depended upon for power, and that the Bann should be developed next if dependence was to be placed on that district for power, but he suggested that the industries should be placed alongside the River Erne and the power used in that district. At least 10,000 horse power could be utilised for the manufacture of carbide, which would profitably employ hundreds of men and would be of the greatest possible benefit to Ireland.

MR. FLETCHER, in thanking the speakers for the reception accorded to his paper, said that he fully realised its defects, which were largely inherent in a short paper dealing with a big subject. Dr. Harker doubted whether it was possible under the meteorological conditions in Ireland to secure peat containing only 25 per cent. of moisture, which he pointed out was drier than the peat obtained in Italy. He was afraid Dr. Harker was not acquainted with the fickleness of an Irish climate. It was impossible to say what degree of dryness might be produced in a single season in Ireland. Sometimes peat was obtained that was much drier than 25 per cent. and sometimes less. Of course, he would not like to trust to a rough estimate made by a peasant, who only knew what he called "good" and "bad" peat, and if asked whether it contained 25 per cent. or 30 per cent. of water no very clear information would be obtained from him on the subject. In some seasons, however, peat drier than 25 per cent. was obtained. It was necessary to take some standard for what was commonly and loosely spoken of as "air-dried peat," and 25 per cent was a convenient figure for the purpose. He was quite aware of the vast importance of the nitrogen content, but as his paper did not deal with the by-products of peat he carefully refrained from saying anything about that vitally interesting question. He might say, however, that the nitrogen content of Irish peat compared very favourably with that of almost any other peat, some of the Irish bogs having quite a high nitrogen content. It had been suggested again and again that in those cases where peat was used in producer plant the by-products should be utilised. At present the by-products in the case of the Portadown installation were thrown away and an output of a certain magnitude was required before it was possible to deal with them economically; but he had no doubt that the economics of a large and well-considered scheme would be considerably affected by the return obtained from the by-products. Dr. Crowley had suggested that, after water power, coal was the next source of power that should be developed. Personally, he did not know on what grounds Dr. Crowley rejected peat, because he was quite satisfied that there was great hope for its economic utilisation, and he thought there was

a much greater hope since the Water Power Report had been issued, because one scheme would considerably help the other. The Peat Committee Report advocated air drying with a minimum of handling, and he thought it was quite likely that large peat stations would be erected. As Dr. Crowley pointed out, a large quantity of water had to be dealt with, but that had been taken into consideration in the scheme that had been suggested. The water would be got rid of by air drying.

DR. CROWLEY said the only point he had made related to the order in which the schemes should be carried out. Personally he thought that coal should be dealt with before peat.

MR. FLETCHER said he was not prepared to accept that suggestion. It was necessary to consider the geography of the coalfields. The Leinster coalfield was the most promising, and that contained anthracite coal which was used almost entirely locally. Until the line was built, by means of which Castlecomer was joined up with the local line, the bulk of the output from Castlecomer was distributed in carts and motor lorries to Kilkenny and the surrounding towns. At the present time if anyone in Dublin desired to get a load of anthracite for domestic use it was difficult to obtain it. He had often wondered why more of the Kilkenny anthracite was not distributed. It was entirely a matter of competition with other coals and other fuels, and in that connection it must be borne in mind that the cost of winning Irish coal was very considerable. In reply to Mr. Theodore Stevens, who had referred to the large amount of calcium cyanamide imported into this country, he was happy to say that there were two calcium carbide factories in Ireland. The further stage of conversion into cyanamide was an important process, and, as had been stated, that was one of the industries which might be developed in Ireland. The three essentials for the manufacture of calcium cyanamide were power, a suitable carbon and limestone. Underlying nearly all the Irish bogs there was a good limestone; anthracite was mined in the country, and a source of power existed in the bog itself, so that he thought there was a very promising field waiting to be developed.

THE CHAIRMAN, in moving a very hearty vote of thanks to the author for his excellent paper, said that, in spite of the great disadvantage from which he had suffered in its preparation and delivery, he had read an admirable, well-balanced paper on three very difficult subjects.

The resolution of thanks was carried unanimously and the meeting terminated.

NOTICES.

CHAIRMANSHIP OF COUNCIL.

ON MONDAY, JULY 10TH, at their first meeting in the new Session, the Council elected Lord Askwith, K.C.B., K.C., D.C.L., Chairman for the ensuing year.

CLOSING OF THE LIBRARY.

Owing to the work of renovating and decorating the Society's house, the Library and Reading Rooms will be closed until further notice.

PROCEEDINGS OF THE SOCIETY.

INDIAN SECTION.

SIR GEORGE BIRDWOOD MEMORIAL LECTURE.

FRIDAY, MAY 26th, 1922.

THE RIGHT HON. VISCOUNT PEEL, G.B.E.,
Secretary of State for India, in the chair.

THE CHAIRMAN, in introducing the lecturer, said that Sir Thomas Arnold was well-known as the greatest authority on the Muhammadan religion that this country possessed.

The lecture delivered was

INDIAN PAINTING AND MUHAMMADAN CULTURE.

By SIR T. W. ARNOLD, C.I.E., D.Litt., M.A.,
Professor of Arabic, School of Oriental Studies.

Those of us who had the privilege of hearing the two former Sir George Birdwood Memorial Lectures have been led to associate with this foundation orations upon some of the weightiest problems connected with the Indian Empire, set out with all the dignity of finished oratory and replete with the wisdom and knowledge of publicists

of ripe experience. A mere pedant might well hesitate to follow where Sir Valentine Chirol and Sir Edward Grigg have given such a distinguished lead, but I take encouragement from the thought that the subject I have chosen is one that would have been of interest to Sir George Birdwood himself. He was one of the first to draw attention in this country to the minor arts of India, and Indian paintings had hardly been studied at all when he pronounced the judgment that they were equal in merit to the paintings of the same age in Europe. Indian art was of interest to him as an expression of personality, and his enthusiastic love for the Indian people caused him to take delight in any manifestation of their artistic activity that brought him into touch with their daily life or in any way aided insight into their ideals. No aspect of their thought or behaviour was without interest for him, as those who enjoyed the privilege of his personal friendship will well remember, and, thus, though you may be disappointed in a lecture that falls so far below the lofty aim of those to which you have listened on previous occasions, I have selected my subject as being one which I know would have gained the approval of the great man in whose memory this annual lecture was instituted.

The modern student of history is accustomed to an ever-widening definition of the subject of his study. History has long ceased to mean to us merely political history, and the rise and fall of dynasties. The modern historian recognises the interaction of innumerable factors—religious, economic, social; disease has been brought in to explain the decay of the influence of ancient Greece, and the austerity of the Catholic Counter-Reformation; art and literature are recognised as important factors in the development of a people. Consequently, the historian nowadays throws his net wide to gather in

material for his account of any period, and no longer confines himself to the written record of the chronicler. One of the results of this wider outlook has been the use of illustration even in serious works of historical research. In this respect French and German scholars have shown the way, for such aids to the understanding of history have found little favour in this country except in school books and popular histories. But those who despise illustrations in books of history may well be reminded that for the primitive periods of the life of humanity, pictures are our only historical documents, and that without the cave drawings we should know little indeed of the life of the earliest inhabitants of Europe. The invention of writing for a long time caused the importance of all other kinds of historical documents to become obscured; but now even the most eminent British historians are beginning to follow the lead of their Continental colleagues in the use of pictorial illustration.

The purpose of my lecture, then, is to suggest some of the directions in which research into the history of Muhammadan India may be pursued, so as to throw fresh light upon aspects of Muhammadan life and thought that the historians have hitherto neglected. Now the study of India is our peculiar domain; no country in Europe possesses so rich a store of material for the purpose in records and manuscript documents of all kinds; written and printed sources are indeed receiving attention, but hitherto little use has been made of pictures as aids to historical research. The fact that so many of our writers on Indian history attempt to survey the whole field from Vedic times to the present day precludes the possibility of any illustration beyond a few historical buildings and portraits. What we now need in Indian history is an increasing number of monographs, and studies of separate aspects and periods in much greater detail. Possibly, also, a fresh point of view may prove to be enlightening, and may establish the falsity of Sir Henry Elliot's complaint against the Muhammadan historians of India that their annals comprised "for the most part nothing but the mere dry narration of events . . . without any observations, calculated to interrupt the monotony of successive conspiracies, revolts, intrigues, murders and fratricides."

He goes on to say: "Of domestic history we have in our Indian Annalists absolutely nothing; . . . by them society is never contemplated, either in its conventional usages or recognised privileges; its constituent elements or mutual relations; in its established classes or popular institutions; in its private recesses or habitual intercourses."

Even to the student of historical documents, which Sir Henry Elliot collected with such persevering assiduity, this complaint seems strange, because the chronicles and other records, which he made known to us in his monumental collection, the "History of India as told by its own Historians," contain an immense amount of material which, if thoroughly studied, would go far to remove the grounds of his complaint. But these documents are waiting for a more careful examination than they have yet received, and when they have been re-read they will reveal the operation of factors that have been, in some instances, more potent than political activities. For this more careful scrutiny of documents, such pictures as are available may provide valuable suggestions, and I propose to make use of them in order that we may see what they have to tell us of the "private recesses or habitual intercourses" of Muhammadan society.

I shall confine myself here to the later period of the Muhammadan history of India, in the 17th and 18th centuries. For this period the number of pictures available is not large, but they are sufficiently numerous to afford useful indications of aspects of social life to which the historian has hitherto devoted little attention. Nothing like a complete survey of the subject can, of course, be attempted here, as the extent of it is much too vast for the narrow limits of a single lecture, but a few distinctive features may be chosen to serve as indications of the directions in which further study and research may achieve valuable results.

One important aspect of the history of Muhammadan rule in India that has not yet received adequate treatment is the religious life of Islam in its various phases and developments. The local peculiarities of Islam in the different parts of the world in which it has found a footing have attracted the attention of students of religion for several decades, but we still lack any comprehensive work of this kind

dealing exclusively with India. The subject is a vast one, and, of course, many of its peculiar phases find no expression whatsoever in art. But Indian paintings emphasise one aspect of the religious life of Islam in India, which is of prime importance—the reverence for saints and ascetics, the submission by the faithful of their spiritual life to the direction of religious guides and teachers. One outcome of this blind submission to religious authority was the enormous expansion of the Islamic religious orders in India, and portraits of the more famous saints belonging to the various orders are common. The imperial house was not behind any of its Muslim subjects in the reverence that its members paid to saints and ascetics, and we have many pictures that show us some emperor or prince of the royal family visiting a holy man. The equality of all believers in the bonds of faith, which is one of the fundamental tenets of Islam, finds striking exemplification in the reverence paid to the religious teacher—and sometimes, indeed, demanded by him. There is a story told of the Emperor Aurangzeb that on one of his progresses through his kingdom he came to the place where an ascetic lived, and expressed a desire to see him; the holy man refused to leave his house, and sent back a message that if the Emperor wished to see him, he must come himself; and this Aurangzeb did, behaving himself with all humility, in the spirit of true Muslim piety.

These Muslim ascetics, in their desire for retirement, often avoided the haunts of men, and, like the Hindu sannyasis, retired into the jungle. Of one such saint—Miyan Hatim, of Sambhal—it is told that for ten years he wandered about in desolate country, bareheaded and barefooted, never once, during all this time, sleeping on a bed. Another saint, Shaykh Muhammad Ghawth, whose tomb is one of the finest monuments in Gwalior, lived a life of austere asceticism for twelve years in the low hills of Chanar, north of the Ganges, dwelling in caves and living on the leaves of trees. Even after they had settled down, such ascetics would shut themselves up for long periods of meditation, and dwell in a lonely cell or a wood. In the later periods of Muhammadan rule, the tomb of some famous saint would serve as the gathering place of his followers in the same spiritual succession, and great establishments of this kind are scattered all over India.

But it is the solitary ascetic that the Indian painter generally preferred to depict.

Another characteristic feature of the life of these holy men was the state of religious ecstasy, which was induced in various ways, but particularly by religious dancing, or by innumerable repetitions of the name of God, or of some religious formula. The biographies of Indian saints tell us many stories of such ecstatic trances under varying circumstances, but the painters, by predilection, represent those which took place during the mystic dance. This form of expressing religious emotion has met with stern disapprobation from most of the orthodox theologians of Islam. The mystics have sometimes allowed it, sometimes looked upon it askance. But in India, despite all hostile criticism, dancing and other external manifestations of ecstatic emotion acquired a considerable vogue in religious circles, especially among the members of some of the religious orders.

These mystics defended such violent expressions of emotion by stories told of the Companions of the Prophet, one of whom hearing a man recite the words of the Qur'an, "Verily the punishment of thy Lord surely descends: there is none to hold it back," (52, v. 8) uttered a loud cry and fell down in a faint; he had to be carried into his house, and lay sick there for a whole month. Many such stories were told of the later saints also—how, under the stress of religious emotion, when the heart was thrilled with rapture and their ecstasy overpowered them, they would shriek and faint, or even die straightway. Such stories found special favour in India, and many of the Indian saints became famous for their ecstatic moods and especially for their habitual observance of the practice of dancing. Of Shaykh Aziz Ullah (ob. 1567) it is said that in his ardent longing after God he wept so continually that the world has never seen the like: as soon as the sound of a holy song or chant fell upon his ear, the effect was like that of a tempestuous wind; every morning and evening he would work himself up into a state of ecstasy, and his example was so infectious that it was said of him that could a flint have looked upon him on such an occasion, it would have become softer than wax. If such miraculous influence were lacking, other mystics, such as Shaykh Fakhr ud-Din (his contemporary), would accept no excuses from the spectators, and would insist upon

all present joining him in the dance.

So far we have considered only some of the religious observances of the Muslims themselves, but the painters draw our attention to the relations that were established between the dominant faith of Islam and the beliefs of the Hindus. The hostility of Islam to the idolatrous system of Hinduism is one of the most obvious features of the relations between the Muhammadan invaders and the earlier inhabitants of India. But the brutal massacres of Brahmans, and the looting and destruction of temples that marked the raids of Mahmud of Ghazni, could not possibly remain as a permanent feature of the conquest, after the invaders had once settled down in the country. Some *modus vivendi* had to be established, and the historian of India has yet to enlighten us as to the extent of the toleration that Islam extended to Hinduism, — upon what theoretical foundation it was based, and how it operated in practice. We want to know not only what was the practice of the State and of the officials of Government, but also the personal relation of individual members of the rival faiths. In this connexion one of the most interesting figures in the Muhammadan history of India is Dara Shikoh, whose disastrous failure to defeat his brother in the struggle for the throne is one of the tragedies of Muhammadan history. He appears to have been animated with somewhat of the spirit of his great-grandfather, Akbar, in attempting to bring about some form of reconciliation between Hinduism and Islam. It is strange that no historian has yet attempted to write a separate biography of Dara Shikoh; for he possesses something of the same pathetic attractiveness as Frederick II. Hohenstaufen; both were princes of enlightened and tolerant religious views; both of them devoted sympathetic study to the doctrines of a creed that was not their own. They paid the penalty of a liberality of spirit in advance of their age, and were wrecked on the rocks of a pitiless fanaticism. Had Dara Shikoh met with success in his efforts to draw the adherents of the rival creeds of Islam and Hinduism together, by emphasising the doctrines and the philosophic conceptions that both Hindus and Muhammadans could hold in common, the history of India might have been very

different. He cultivated the society alike of Muslim saints and Hindu sannyasis, and, approaching his own faith from the stand-point of Sufism, he came to the conclusion (as he states in one of his writings) that the divergence between the doctrines of the Hindu pantheists and those of the Muhammadan mystics was verbal only; and he wrote a book, entitled "The Confluence of the two Seas," with the object of reconciling the two systems.

Among the Hindu Yogis, whose society he frequented, the name of one, Baba Lal, has been recorded. This ascetic settled near Sirhind, in the Panjab, where he built himself a hermitage by the side of a temple. He gathered round himself a large number of disciples, and among those who were attracted by his teaching was the young prince, Dara Shikoh. Two learned Hindus, who were in his service, put down in writing a record of the conversations that took place between him and Baba Lal on several different occasions in the year 1649 when Dara Shikoh, who was then aged 34, visited him, and these dialogues are still extant in manuscript, but have never been printed. Such friendly intercourse between members of the rival creeds, sundered from one another at times by rivers of blood, stands out as one of the most attractive chapters in the religious history of India. Art comes in here to establish the existence of what some historians have believed to be impossible. It is strange indeed how little attention it has received, and it still remains for some student of religion to collect together such instances as may be found in the *Acta Sanctorum* of Hinduism and Islam. One example may be given here from the legend of two ascetics in the Panjab, Dial Bhavan, a Hindu saint, and Jamali Sultan, a Muhammadan. Their tombs still stand close together at Girot, as a symbol of the friendship that united them in life. Of their first meeting a story is told—which appears, indeed, in various forms in other hagiologies — how Dial Bhavan was already settled with his disciples in Girot at the time when Jamali Sultan arrived there. Dial Bhavan sent to the newcomer a vessel of milk filled to the brim, as a delicate hint that the town was already full enough of ascetics, and that he would be well advised to settle elsewhere. Jamali Sultan understood the message perfectly well, but won for himself a welcome by sending back the brimming vessel,

* The lives of these saints have been made accessible to the English reader by Sir T. Wolsley Haig's translation of *Al-Badaoni's Muntakhabu 't-Tawarikh*, Vol. III. (Calcutta, 1899.)

with a rose-petal floating on the surface of the milk.

We must now pass on to other characteristics of the life of the Indian Muhammadans to which their painters direct our attention. Their art was in the main a courtly art. They painted for the emperor and for the nobles, upon whose patronage they depended for their livelihood. The artist, during the period we are considering, was generally attached either to the royal atelier, which must have been a very large establishment, or was in the service of some wealthy lord. The subjects, therefore, that these painters selected were generally such as had reference to the life of the court, or were of interest to their princely and other patrons.

Of one important section of their work, the paintings of darbars, I do not propose to treat here. Many of these darbar pictures have already been published, and the subject of the darbar, its arrangement, its importance in the organisation of a despotic government, such as was that of the Mughals, have been already studied, —though still inadequately. But of the life of the nobles, apart from their daily attendance at the imperial darbar, and their respective official duties, civil and military, no detailed study has yet been attempted.

On the present occasion it is only possible to make selection of a few of the features of this court life. As is well known, it was one that was governed by strict rules of etiquette. No one has yet attempted to show how the rough, careless Muhammadan invaders of India, after they had firmly established themselves in that country, introduced such polished manners into their court, and elaborated the rules of social intercourse almost into a fine art. The grace and charm of cultivated Muhammadan society form a part of the inheritance of the past, which the Indian Muhammadans of the present generation tend to despise as old-fashioned. But those who have been privileged to know any Muhammadan gentlemen of the old school will remember how their courteous behaviour, combined with personal dignity and self-respect, added charm and attractiveness to social relations with them.

Much of this etiquette, and the culture that went along with it, derived its origin from Persia, for (as is well known) since the time when the Mongol invasions brought ruin and devastation to Central and Western Asia, and destroyed so many centres of

Muhammadan culture, refugees fled, in large numbers, into India, for there Muhammadan kingdoms were still stable and safe from the flood of destruction that had overwhelmed so many other Muhammadan states. Among these refugees, Persians formed a large proportion, and Persian poets, men of letters, religious teachers and others exerted a permanent influence on the culture of Muhammadan India. The official language was Persian; in Persian was written the major part of the prose literature and practically all the poetry. Under such a centralised government as that of the Mughals, learned Persians, lawyers, physicians, artists and others, who depended for their livelihood on the patronage of the court, naturally flocked to the capital, and succeeded in winning for themselves an ascendancy in all positions that called for intellectual attainments. The Hindus, it is true, were capable of being their intellectual rivals, but the Afghans, who constituted the other great group of Muhammadan immigrants, were too rough and illiterate to gain much distinction in civil life, and the Persians accordingly came to the front not only in the learned professions, but also filled some of the highest offices in the state. A typical example of such a Persian is Ala ul-Mulk Tuni, who rose to high office under Shah Jahan; he first showed his ability in the ministry of finance; then he was raised to the important post of superintendent of the examination of petitions, and was lastly made Lord High Steward,—an office that placed in his hands the control of the whole expenditure of the royal household. When Shah Jahan was dethroned by his son, Aurangzeb, the new emperor, aware of the fidelity of his father's minister, took him into his own service. Aurangzeb reposed so much confidence in him that he placed him in charge of the deposed sovereign and of the enormous establishment that he was allowed to keep up as a symbol of his former grandeur. Before his death, Ala ul-Mulk had been raised to the highest office in the state, as chief minister. In spite of having had so varied an official career, he found time for the cultivation of intellectual interests and was proficient in mathematics, astronomy and natural science.

Ala ul-Mulk Tuni may be taken as a typical example of the refining influence of Persian culture—the cultivated gentleman, with polished manners, intellectual

interests, bringing the ripe fruit of a trained intelligence and of a mature experience to bear upon the affairs of the state. Hundreds of such examples might be given to show how profoundly Persian culture interpenetrated every section of Muhammadan society in India.

The other great contribution to Indian Muhammadan culture came from Hinduism, and some measure of its influence may be found in the degree of the approximation of the two systems. The great example of the spirit of conciliation and harmony between these rival systems of life and thought in India—Hinduism and Islam—is, of course, Akbar. The failure of Akbar's great attempt at reconciliation has obscured the recognition of the close approximation between Muhammadan and Hindu society that shows itself clearly during succeeding generations, in manners pre-eminently, and to a considerable degree also in habits of mind and intellectual interests. It is in literature that the most striking evidence of the Hindu contribution towards this approximation is to be found; the Muhammadan influence expressed itself largely in externals, and here art may come to the assistance of the historian, for innumerable pictures of Hindu rajas and their surroundings reveal how profoundly they had become impressed by the Mughal Court, and how largely Muhammadan influences had come to form part of their daily life and manners. The most obvious and visible sign of such approximation between Hindu and Muhammadan culture was costume, and the court dress of the Mughals was not only adopted by many of the Hindu rajas, but even survived longest in Hindu courts; one of the last persons to wear this dress was the late Raja of Bundi, who appeared in it at the Delhi Durbar of 1897, to the amazement of a generation that had almost entirely forgotten the Mughal Court and its fashions.

It is strange that in the vast literature on the history of costume that of Muhammadan India hardly finds a place, in spite of the abundant materials available in the great series of historical portraits to be found in our libraries and museums. As those portraits are better known than almost any other section of Indian Muhammadan painting, I do not propose to dwell upon them here. But to the examples already given, I would add only one which shows the extent to which the skirt became

lengthened in the 18th century. It represents Shuja ud-Daulah, the Nawab of Oudh, and his sons. This singular dress is typical of the effeminacy which prevailed in the Muhammadan courts in India during the period of their decline. It finds characteristic expression in the exclamation of the last Nawab of Bengal, when, in the year 1765, he ceased to be even a titular ruler and became a pensioner of the East India Company: "Thank God, I shall now have as many dancing girls as I like."

To this more frivolous aspect of the court life, let us now turn. The question of the place occupied by the dance in Muhammadan society is of great interest, but it still awaits the attention of the sociologist. It has its religious aspect, in the devotional exercises of the religious orders and the practices of the Sufistic mystics, and as we have seen, there are several Indian representations of such religious dances. Here I shall make brief reference only to its lighter aspects, as represented in Muhammadan painting. How large a part the dancer filled in the life of the later Muhammadan princes and nobles is shown by the fashion that grew up after the death of Aurangzeb for these great personages to have their portraits taken while engaged in watching a dance. We no longer have the austere picture of the noble of the early period of the great days of Mughal rule, standing alone, dignified and erect, or leaning on his sword. But a new convention is introduced in which the noble is no longer shown in the guise of a warrior or statesman, but we see him enjoying his hour of ease.

There is a long series of portraits of this type in which a singer or a dancing girl, either with attendant musicians or with other dancers, displays her art before the prince or noble. It would appear that towards the close of the Mughal period this became an established convention in the art of portraiture, just as the Italian or Flemish noble of the 15th century had himself painted as kneeling before the Madonna, or the Tudor gentleman held in his hand a pink or some other flower, or the mid-Victorian gentleman stood with one leg elegantly crossed before the other. The Muhammadan convention was more picturesque. Unfortunately, as the majority of Mughal portraits are unnamed, it is often difficult to identify the personage represented; but it was a fashion that found favour with even the highest, and one

such picture represents so exalted a prince as Asaf Jah, the first Nizam of Hyderabad (1724-1748).

Many of these pictures are graceful and pretty; the bright colours employed (of which I shall speak later) give them an extraordinary brilliancy, and these colours are set off by broad spaces of white, such as a smooth marble platform, or a white-washed wall. They are also often worked out in much more elaborate detail of accessories than is the case with the more simple and more dignified Mughal portraits of the earlier period.

Another characteristic feature of the life of the Mughal court, which receives abundant pictorial representation, is drinking. As is well known, drinking may almost be called the family vice of the Imperial family. Babur, the founder of the house, has himself put on record the story of his wild drinking bouts, and his descendants showed a similar disregard of the injunctions of the founder of their faith. Humayun preferred opium; Akbar drank both wine and opium; his son Daniyal died of delirium tremens; his heir, Jahangir, flouted orthodox Muhammadan sentiment so far as to strike coins representing him with a drinking cup in his hand, and in his memoirs gave detailed accounts of his drinking bouts. Aurangzeb tried in vain to check these habits of drunkenness and (with the exception of his namesake, Alamgir II., who reigned 50 years after him), was the only one of the Mughal emperors who did not drink. When the rulers thus set the fashion, it is not surprising that the nobles of their court followed their example, and it became quite common for a grandee to have his portrait taken with a wine cup in his hand. Representations of indulgence in other intoxicants occur less frequently. Though the taking of opium was a fairly common practice, it does not appear to have been selected as a subject for pictorial art. On the other hand, the drinking of Bhang, or Indian hemp, often appears, especially in pictures of sannyasis; but as we are only concerned here with the life and manners of Muhammadan society, no reference need be made to Hindu habits. There is preserved in the British Museum a large picture representing the sale of Bhang in Hyderabad, about the middle of the 18th century. At that period there was a well-known seller of Bhang named Matvali Bhang-saz, who received a

gold mohur from every customer to whom she handed a cup with the right hand, and a silver rupee if she handed it with the left. This painting gives a lively picture of various types of persons in the Muhammadan society of Hyderabad at this period. We see here the soldier blustering and quarrelsome; the nobles of the court; even dignified respectable members of society have succumbed to the attraction of the pernicious drug.

The prevalence of habits of drunkenness among the higher circles of Muhammadan society makes one wonder how they managed to preserve their health, but, like the English squires of the 18th century they spent much of their time in the open air. They lived in a period of constant warfare, and so the Mughal emperors and their nobles spent a great part of their lives in camp. When they were free from the operations of war, their great amusement was hunting. For this side of their life, there is abundant documentary evidence, and painting supplements the written record.

Let us pass now from drink to food. No serious student of history can undervalue the importance of food in the social economy of mankind. The satisfaction of this primitive need is one of the foundations on which the fabric of organised human society was built, and no study of even the most highly developed civilisation is complete without reference to this source of its continuance in existence. But apart from these economic considerations, there is the important place that food takes in the daily life of any advanced society. Every student of Muslim political history knows how close may be the connexion between an outburst of fanaticism and the month of Ramazan, and the administrator in India is unlikely to belittle considerations of diet. But art has little or nothing to say in reference to these larger aspects of the question, particularly as the school of painting we are now considering is, above all, a courtly art. But in this narrower sphere of the court, a fortunate chance has preserved for us a manual of cookery, compiled for the use of the Imperial household, and as it has hitherto remained unnoticed, some account of it may be of interest here. The date of the MS. is uncertain; but it cannot be more recent than the reign of Shan Jahan (1628-58), and it may, indeed, be earlier. The pictures in the manuscript show that the Master of the

Imperial Kitchen was a person of considerable importance; he took himself seriously, assumed airs of superiority and dressed like a gentleman in authority, and from what we know of the numbers of the persons who lived in attendance on the Mughal emperor and were fed at his expense, we may form some idea of the difficulty which would be experienced by any one who had to cater for them. In Akbar's palace there were more than 5,000 women, and even in Aurangzeb's there were as many as 2,000, and to these large figures we must add the male members of the establishment before we can arrive at the total number of all those who had to be provided with meals. Abu'l-Fazl tells us that meals were being carried from the imperial kitchen into Akbar's zenana all day long, from early morning to nightfall. Further, if we take into consideration the precautions that an oriental monarch had to take, in view of the risk he ran of possible attempts to poison him, we may realise the importance of the officer who was placed in charge of the kitchen. Hakim Human, who held the office of Master of the Kitchen in Akbar's reign, was a close personal friend of that emperor, and exercised considerable influence at court, and was sent by him as ambassador to the Shaybanid Khan of Transoxiana. Akbar himself was a very moderate eater, and contented himself with only one meal a day, and used to rise from the table before he had fully satisfied his hunger; the cares of state, and his many intellectual interests might well have left him no time to devote to the business of the kitchen. But his biographer tells us that Akbar himself drew up regulations for the conduct of this department, and interested himself in the working of it. How many assistants were assigned to the kitchen we are not informed, but, in view of the enormous household for which meals had to be provided, the number of cooks employed must have been considerable, and beside the cooks, there were tasters and a number of other servants, and with so large a staff we may well imagine that difficulties of discipline might arise. The kitchen had its own treasury and accountants; a budget was drawn up at the beginning of the year, and accounts were submitted every month. The dishes were served up with considerable ceremony. Spectators and idlers were excluded from the kitchen or the place where the cooking was carried

on (for, as we shall see, it often took place in the open air). As soon as the food was taken out, it was tasted by the cook and the assistant to the Master of the Kitchen who happened to be in charge of this particular section; then it was tasted by the Master of the Kitchen himself, and put into the suitable dish. The gold and silver dishes were tied up in red cloth, and the copper and china ones in white cloth. Then the Master of the Kitchen affixed his seal to the cloth wrapper, and wrote out a list of the contents of each dish; the dishes were then carried into the royal apartments in procession, with macebearers walking in front of and behind the cooks. The servants of the palace, who broke the seals and arranged the dishes on the table cloth, had also to taste the food, and the Master of the Kitchen had always to be in attendance while the Emperor took his meal.

I conclude my lecture with one more example of the way in which Indian painting may add to the knowledge which we gain of Muhammadan society from written records. In this instance, the evidence I have to present is rather of a negative character; it has to do less with illustrations of contemporary life than with a frame of mind that turns away from the horrors of the present to a dream world of imagination.

In the reign of Muhammad Shah (1719-1748), during the early decades of the 18th century, there appears to have been a short-lived renaissance of Indian painting.

The painters of this school were living in an age that was rushing to its ruin. The Mughal Empire was breaking up; the raids of the Mahrattas rendered life and property insecure. It was unsafe for women to go to the wells outside the city walls for fear of being carried off by marauders. The weakness of the central government left the taxpayer a victim to any local magnate who could attract to himself a body of mercenaries, and life was full of uncertainty and anxiety. These pictures were painted before the crowning horror of Nadir Shah's invasion in 1739, but this disaster, followed a few years later (1756), by the invasion of Ahmad Shah Durrani, struck the death knell of Mughal culture, and painting perished with other arts that lived on the patronage of the court.

The painter of this period no longer goes to sober history or to contemporary personages

for the subject matter of his pictures; he adds nothing to our knowledge of the times he lived in, for he turns from the miseries of the troubled period in which he finds no outstanding figures to paint, and takes refuge in the realm of fancy. He illustrates fantastic romances, full of fairies and strange monsters, and the adventures of imaginary lovers moving in an unreal world.

This school of painting represents the last effort of Mughal art. Apart from its special choice of subject matter, it has certain distinctive features of its own—brilliancy and vividness of colouring, set off by large white spaces—and is in pleasing contrast to the somewhat drab, uninteresting colouring of many Indian paintings since Aurangzeb's puritanical attitude towards art had withdrawn the imperial patronage from painters, so that painting suffered a miserable decline for a half a century.

It would be easily possible, did time allow, to add to the aspects of history in regard to which Indian paintings may increase our knowledge of Indian Muhammadan society in its various phases, or may suggest new lines of research that have hitherto been neglected; for there is a rich store of such material lying unregarded in the great collections of this country; they have received some attention from students of art, but have as yet been little studied as historical documents.

[The lecture was illustrated by a number of pictures, taken from albums and manuscripts in the British Museum, the Bodleian Library, Oxford, and the Library of the India Office; the greater part came from the last-named Library, which possesses in the collection made by Mr. Richard Johnson about the end of the 18th century, abundant examples of the later schools of Indian painting.]

DISCUSSION.

THE CHAIRMAN (Viscount Peel) said it was with very great pleasure that he moved a hearty vote of thanks to Sir Thomas Arnold for the very learned, illustrative, entertaining and instructive lecture which he had given. The lecturer had reminded them that historians had discarded their ancient formalism, and were ready to search for materials in many quarters which before would have been regarded as unworthy of the dignity of history. The muse of history to-day was no pedant; she shortened and lengthened her skirts according to the fashion. It was realised nowadays that for the purpose of interpreting and illustrating

contemporary habits, a washerwoman's bill might be of far greater service than the report of a debate in Parliament, and the gossip of the drawing room or the Bazaar of more use than a learned treatise on Hegel. It was obvious from the lecture that many interesting parallels could be found between the habits of the East and the West. The lecturer spoke of ecstasies of religious emotion, sometimes condemned and sometimes applauded by the religious men of the day. That might be compared with many exhibitions and varieties of religious experience seen in the West, and perhaps more particularly in the United States. The lecturer had spoken of the Emperor Aurangzeb humbling himself by going to the house of an ascetic: but there was a famous Emperor of the West who knelt for days and nights in the snow before the castle of a Pope. Personally, he had been greatly interested in what the lecturer had said with regard to religious toleration, the efforts made to reconcile the differences between the observances of the Hindu and Muhammadan religions, and the attempt made by Dara Shikoh to lessen the acerbity which prevailed between them. At the present time, in a neighbouring island, it was being shown what religious intolerance was capable of. A parallel could be found for the elaborate etiquette of the Mughal Courts in the elaborate formalism introduced by Louis XIV. He had formed the impression that the lecturer preferred realism in Art, because he spoke with some irony of what he described as "imaginary lovers wandering in unreal woods." Personally, he thought a touch of imagination might be acceptable after the realistic scenes of dinners and festivities which had been depicted. The chief service the lecturer had rendered was not in pointing out that history was gathered from many sources, pictorial as well as written, but that he had shown to students so many fascinating opportunities of pursuing fresh studies. There would be, no doubt, a growth of useful monographs as the result of suggestions made in the lecture. He would ask Lord Ronaldshay to second the vote of thanks. Every one present would be glad to see him back in this country, looking fresh and vigorous after his highly successful five years as Governor of Bengal.

THE EARL OF RONALDSHAY, G.C.I.E., said he was delighted to associate himself with everything the Chairman had said with regard to the lecture. Personally, he thought one of the most interesting subjects on which it touched was the extent to which the beliefs and practices of Muhammadanism and Hinduism had tended to come together and coalesce as a result of their contact on the soil of India. That, he thought, was a matter not merely of academic interest, but of practical importance, in that it gave some idea of the extent to which a synthesis

between the civilisation and culture of the other two great divisions of mankind—Indians and Europeans—was possible. No one who had had the opportunity of assessing the growing love which educated Indians to-day felt for their past would be likely to under-estimate the importance which that question had upon the relations of this country with India. The lecturer had called to his aid the pictorial evidence of the XVIIth and XVIIIth centuries, and made it quite clear that reverence for saints and ascetics, and the acceptance by the faithful of guides and leaders for the formation of their spiritual life, had become a feature of Muhammadanism in India at that time. He (Lord Ronaldshay) was not sufficiently acquainted with the practices of Muhammadanism in other countries to be able to say whether that characteristic might be regarded as a distinctive feature of Indian Muhammadanism, but he could well believe that its development received a tremendous impetus from contact with Hinduism, because the idea behind it was essentially a Hindu idea. An instance occurred recently in Eastern Bengal of Muhammadans worshipping their saint, entirely in accordance with the traditions of Hinduism, but in a way repugnant to the essential teaching of Islam. He should perhaps add that there might have been more policy than piety behind their actions, since the "saint" in question happened to be a notorious local leader of the Non-Co-operation movement. Another striking example of the way in which Hinduism had influenced Muhammadanism in Eastern Bengal was brought to light by the investigations of the Calcutta University Commission. It was found that a large proportion of the Muhammadan students at a large school in Eastern Bengal believed in the doctrine of Karma and re-birth, an essentially Hinduistic idea. The lecturer had mentioned the attempts, abortive though they were, of Akbar to bring about a synthesis between Hinduism and Islam, and had spoken at greater length of similar attempts, equally abortive, made by Akbar's great-grandson, Dara Shikoh. It would appear at first sight, therefore, that little in the way of a real reconciliation had taken place between those two great different worlds of thought, practice and belief, in spite of the many centuries during which they had been practised side by side in India. He could, indeed, say without hesitation that any one who had been called upon to take part in the administration of India, in any part of the country where Hinduism and Muhammadanism were practised side by side, must know of the profound antagonism which existed between them, and which was likely at any moment to break out into open violence. He did not think, however, that those who pinned their faith to a synthesis springing up between all that was best in the civilisation and culture of the East and West need be unduly

depressed by the apparent width and depth of the gulf which still yawned between Muhammadanism and Hinduism in India. It was by no means certain that the impact between the polytheism and pantheism of Hinduism and the pure and aggressive monotheism of Islam had not left behind it something permanent; it was surely the ferment of ideas created by that impact which found expression in the teaching of two great Indian thinkers of the XVth century, Kabir and Nanak, and it was the new ideas expressed by those two men which in due course produced that great, important and distinctive community, the Sikhs. At any rate, it was arguable that that was so. Sir Thomas Arnold's admirable lecture contained a great amount of food for thought, and he had much pleasure in seconding the vote of thanks to him.

The resolution was then put by the CHAIRMAN and carried unanimously.

SIR CHARLES S. BAYLEY, G.C.I.E., K.C.S.I., proposed a hearty vote of thanks to the Secretary of State for India for attending the meeting and occupying the chair. By doing so, he had paid a fitting honour to the memory of Sir George Birdwood, to whom India and Indian art owed so much. He had also paid honour to the lecturer and to the Royal Society of Arts by his presence that afternoon. The then Under-Secretary of State for India, Lord Lytton, had presided over the lecture delivered by Sir Edward Grigg last year, and it was hoped that the precedent thus created would be followed in future: nothing could be more appropriate than that the highest representative of the India Office should preside over these lectures. Sir George Birdwood was associated with India and the India Office for many years, and no tribute could possibly be more gratifying to him than that his memory should be honoured in that way, and that his services in bringing to notice the products, art and ancient civilisation of India should thus be recognised.

SIR VALENTINE CHIROL said he esteemed it a great honour and privilege to second the vote of thanks to the Secretary of State for presiding on an occasion which recalled in the best possible way, and in the manner which would have been most acceptable to Sir George Birdwood himself, the memory of a man who was a devoted friend and lover of India. All those present were very grateful to Viscount Peel for having spared the time from his onerous duties at the India Office to preside over the meeting.

The vote of thanks was passed and the meeting then terminated.

NOTES ON BOOKS.

INDIAN STANDARD LOCOMOTIVES (5' 6" Gauge)

By H. L. Cole, O.B.E., M.I.Mech.E. Calcutta :
Superintendent Government Printing, India.
1922 Rs. 5.

This volume forms the two-hundred and twenty-ninth "Technical Paper" issued by the Indian Railway Board, though it is notified that neither the Board nor the Government of India accept responsibility for statements made or opinions expressed by the author. As locomotive development in India is at present entering a new phase, Mr. Cole, who is Secretary to the Railway Board, considers the moment opportune for a review of the main features of the existing standard designs. When those designs were initiated some twenty years ago the fuel requirements of Indian railways were still largely met from the United Kingdom, but with the development of the Bengal fields the importation of British coal was rapidly diminishing. Eventually the change over from British to Indian coal became complete. At that time sufficient quantities of the best Bengal coals were available, but since then the fuel position has been entirely altered. The increasing need of the better Indian coal for shipping and industrial, particularly metallurgical, purposes has compelled the railways to rely upon the poorer qualities. "The inevitable corollary to this is that if the efficiency of the train service is to be merely maintained—and we should rather look forward to its being steadily improved—our locomotive boiler design must be adapted to suit the fuel conditions." It is interesting to learn that while the known supply of first class Indian coal is limited that of second class is, to quote the author, abundant and only awaits development. One important factor in the consideration of the question of standardisation policy is specially emphasised by Mr. Cole. "India," he writes, "possesses dangerous land frontiers. It is a necessary insurance, therefore, that provision should exist for the possible necessity of having to effect a great military concentration at any time and at short notice. Locomotives of 5' 6" gauge cannot readily be borrowed from abroad and there would be no time to build them. But India cannot afford to maintain an idle reserve of locomotives awaiting such an emergency. The demand when it arises must consequently be met from existing resources, in other words, from various railways all over India." For all the reasons so elaborately set forth it is submitted that "the time is ripe for considering first the possibility of modifying certain existing standards with a view to increasing both capacity and efficiency." The text is illustrated by a large number of plates (photographs) and diagrams.

THE ASBESTOS MINING INDUSTRY OF QUEBEC.

The asbestos deposits of the Province of Quebec, which furnish at present between 85 and 90 per cent. of the world's supply of that substance, are found in a long and narrow zone of serpentine rock which enters Canada from the south, near Lake Memphremagog, and extends in a north-easterly direction, with more or less break, into the Gaspé Peninsula. According to a report by the United States Vice-Consul at Montreal, the workable deposits, so far as known at present, are confined to (1) that part of the zone which extends from Coleraine to East Broughton, for a length of about 25 miles in Megantic, Wolfe, and Beauce Counties, and (2) a small development of serpentine in the vicinity of Danville in Richmond County. There are at present six producing centres—East Broughton, Robertson, Thetford Mines, Black Lake, Coleraine and Danville.

The extreme outcroppings of asbestos ore in the serpentine zone are more than 400 miles apart, the most southerly being near the Vermont border at Mansonville, and the most north-easterly in the Gaspé Peninsula at Mount Albert, in the Weir district, and at Mount Serpentine on the Dartmouth River. A later discovery of an out-cropping of asbestos ore in the Lake Temiskaming district was investigated in 1918 by an official of the Quebec Department of Mines and the presence of veins of asbestos fibre was verified. This prospect is too far from existing lines of communication to offer much interest at present, even if development work on the property reveals the presence of asbestos in economic proportions.

The asbestos extracted from the mines of Quebec is exclusively of the chrysotile variety, the demand for which has within the past few years been greatly augmented by the new uses found for this material.

During 1920 the output of asbestos from Quebec mines amounted to 174,521 tons, valued at 11,758,234 dollars, which is equal to more than 50% of the value of the Province's total mineral production. The corresponding figures for 1919 were 135,861 tons, valued at 10,932,289 dollars.

Practically the entire output of the Quebec asbestos mines is exported, as there is only one concern in Canada manufacturing asbestos products. This factory produces for home consumption and export asbestos slates, shingles, interior and exterior coverings, boards, paper, and undulated asbestos sheets. About 80 per cent. of the asbestos exported from Canada goes to the United States, whence perhaps a small quantity may be re-exported in the crude state. England takes 7 to 10 per cent., and smaller quantities go to Italy, Japan, France, and other countries.

PARAGUAYAN INDUSTRIES AND RAILWAYS.

Paraguay is purely an agricultural and pastoral country and imports almost all of the manufactured goods in use there. Manufacturing on a small scale is carried on in such articles for local consumption as ice, soft drinks, beer, soap, candles, matches, boots and shoes, pottery, tiles, bricks, cigars and cigarettes, sugar, and furniture, and in extractive industries, such as corned beef, jerked beef, quebracho extract, and yerba maté. Owing to the primitive methods in use in most of these lines and on account of their unimportance, hardly any statistics of production are available.

Figures furnished to the United States Vice-Consul at Asuncion by the five principal refineries in Paraguay show that 1920 was the record year in sugar production. They produced 3,639,000 kilos of sugar, 418,917 litres of industrial and rectified alcohol, and 199,101 litres of caña, whereas in 1919 they produced 2,490,397 kilos of sugar, 377,316 litres of alcohol, and 46,350 litres of caña. The annual consumption of sugar in Paraguay is estimated at 3,000,000 kilos. For the first time in the history of that country, sugar amounting to 1,411,037 kilos was exported as follows:—To Uruguay, 980,717; to Argentina, 189,760; and to Spain, 240,560. Paraguay benefited immensely as a result of the prohibition by Argentina of the export of sugar.

Efforts made during the past 50 years to provide Paraguay with means of transportation have resulted in the construction of only 300 kilometres of railway. Outside of this line—the Paraguay Central Railway—which connects at Encarnacion, in the southern part of the country, with the Argentine North-Eastern, the country is in the same condition as it was then. In many cases the lack of communication reaches the point of total isolation.

Most of the foreign commerce of Paraguay depends upon the river traffic for its outlet to the sea. In normal times only a small part of the commerce is handled by the Paraguayan Central Railway, and as the river traffic is monopolised by an Argentine company, any trouble in Argentina is bound to have its effect upon the commerce of Paraguay.

The Paraguayan Central Railway Company is planning to construct various branch lines; one from Paraguari to the Misiones in the southern part of the country; another from Ipacary or Pirayu to the Cordilleras northward, and others that will facilitate the problem of transportation for some of the richest and most thickly populated sections of the country.

FUR FARMING INDUSTRY IN CANADA.

The raising of wild fur-bearing animals in captivity for their pelts has been carried on in

Canada for many years, but it is only within the last few years that fur farming has become an established industry, according to a recently published official report on this subject, quoted by the United States Consul-General at Winnipeg.

In 1912 and 1913 the Dominion Commissioner of Conservation conducted an exhaustive inquiry into the history and possibilities of fur farming in Canada, and the resulting data, published in 1913, stimulated the industry. The fox has proved the most suited to domestication, although success has been attained in a few instances with mink, skunk, raccoons, and Karacule sheep. The earliest record of raising foxes in captivity comes from Prince Edward Island, where they have been raised for the past 40 years.

In 1919 the Dominion Bureau of Statistics began the annual collection of returns of fur farms in Canada. The returns show that 424 fox farms, 3 mink farms, and 2 raccoon farms were in operation in Canada in that year.

The fur-bearing animals on the farms at the end of the year 1919 numbered 8,396, valued at \$3,201,388, comprising 7,181 silver foxes, value \$3,110,915; 852 patch foxes, value \$77,058; 275 red foxes, value \$11,345; 1 gray fox, value \$150; 1 blue fox, value \$120; 77 mink, value \$1,685; and 9 raccoons, value \$115. There were born in captivity, during the year 1919, 5,048 silver, 510 patch, and 184 red foxes, and 40 mink.

The number of silver pelts sold was 2,134, with a total value of \$501,973. This gives an average value of \$235 per pelt of silver fox. Patch-fox pelts sold numbered 319, value \$21,526 (average value \$67), and red fox 164, value \$4,586 (average value \$28). One blue fox pelt was sold, value \$65; 56 mink, value \$1,030; and 2 raccoon, value \$30. The number of pelts sold in 1919 does not correspond with the number of animals killed for pelts, the sales for the year including some pelts carried over from the previous year, while the pelts of some animals killed in 1919 were not disposed of in that year.

Of the 429 farms reporting in 1919, 244 were operated by individuals, 87 by partnerships, and 98 by joint-stock companies.

THE MINERAL PRODUCTION OF ECUADOR.

The mining industry of Ecuador is limited to the production of gold, petroleum, and salt. The total value of the mineral production is not known, as no official records are kept of any of them, but the production remains approximately the same each year.

Gold is produced at one mine situated at Portovelo, in the southern part of Ecuador, near Zaruma. The control of this industry is based on a contract between the Ecuadorian

Government and the producing company. The production in 1921 was 22,224 pounds of metallurgic precipitates, valued at \$774,975, and 1,313 troy ounces of mill bullion, valued at \$4,561. The production is disposed of by more or less regular shipments to the United States, the total production being exported. According to a report by the United States Consul-General at Guayaquil, a considerable sum of money has been expended during the last few years to place this industry in a first class condition, and new veins have been located which are said to be richer than those previously discovered. These mines are rather difficult to reach, as both passengers and goods have to be carried on the backs of mules over the tops of the mountains.

The principal petroleum developments in Ecuador are those at the Santa Elena fields on the west coast. The quantity of crude oil produced is about 4,000 barrels per month. The product of the open wells is of much lower grade than that of the drilled wells, the latter being exceptionally high grade. No accurate figures are available, but it is known that all of the crude product is consumed locally, there being two small refining plants in the district.

A recent discovery of oil shale and petroleum was also made in a district north of Guayaquil and more than 100 miles from the Santa Elena fields.

The salt industry of Ecuador is a Government monopoly. The deposits are found in the region of Payana, Punta Arenas, Salinas, Charapoto, Crucita, Latucunga, Guaranda, and the Galapagos Islands.

Deposits of guayaquilite are found in the Canton of Daule, near the Daule River, and occur over a considerable tract of land. The substance is utilized in the manufacture of explosives. No developments have ever taken place in the district, but apparently the mineral exists in commercial quantities. It belongs to the fossil resins and has the aspect of an impure wax.

Judging from the manner in which the nodules of guayaquilite present themselves disseminated in the alluvial soil along the Daule River, the Consul-General is of opinion that it is not probable that large deposits exist.

THE RAMIE INDUSTRY IN CHINA.

Ramie (*Boehmeria nivea*), also known as rhea and as China grass, is the most important textile plant in China, according to a report from the United States Consulate General in Shanghai. It is grown mostly in the valleys of the Provinces of Hunan, Hupeh, Kiangsi, and Szechuen, to some extent in Kwangtung, and is found in all the warmer parts of China up to 4,000 feet altitude. The ramie from which the finest quality of cloth is made is produced in Kiangsi Province.

Ramie is extremely durable, being of the

strongest and finest fibres known. While slightly lacking in elasticity, it is less affected by moisture than any other fibre. It takes dye readily, and the fibres have a brilliant, silky lustre. In Japan it is prepared to resemble silk thread and is used for the making of artificial silk garments.

The fibre is employed in the manufacture of gas mantles (for which it is particularly well adapted), also for ropes, lines, nets, underwear, canvas, and other similar fabrics. Experiments have also proved that it can be utilized in the manufacture of paper.

The following table shows the amount of ramie fibre exported from China during recent years, as shown by the customs returns:

Countries of Destination	1917	1918	1919	1920
	<i>Tons*</i>	<i>Tons*</i>	<i>Tons*</i>	<i>Tons*</i>
France.....	432	734	135	179
Great Britain.....	1,205	1,445	295	1,309
Hongkong.....	386	642	317	319
Japan.....	14,958	13,658	13,096	10,303
United States (including Hawaii and the Philippine Islands).....	1,337	1,784	25	2
All others.....	84	45	194	356
Total.....	18,462	18,308	14,062	12,468

* Short tons of 2,000 pounds each.

The total value of the exports* in 1917 was £773,000; in 1918, £936,000, and in 1919, £865,000.

The principal points of original export abroad and to other parts of China are Hankow, Kiukiang, and Yochow, in the order named. The city of Swatow receives the greater share of the ramie fibre exported from other portions of China, this city being the centre of the ramie weaving or China grass-cloth production. Swatow and the cities of the Shanghai district receive, approximately, five-sixths of the exports of this commodity. The ramie fibre imported into Shanghai from other parts of China in the year 1919 amounted to 16,190 short tons, of which 2,113 tons were re-exported to other Chinese ports and 13,293 tons abroad.

Exports of grass cloth from China in 1917 were valued at £418,000; in 1918, at £507,000, and in 1919, at £994,000. The following table shows the quantity and destination of exports:—

Countries of destination	1917	1918	1919	1920
	<i>Tons*</i>	<i>Tons*</i>	<i>Tons*</i>	<i>Tons*</i>
Hongkong.....	101	82	82	113
Japan.....	68	100	135	131
Korea.....	820	707	1,472	1,388
Philippine Islands.....	2	1	3	2
Straits Settlements.....	61	61	57	82
All others.....	10
Total.....	1,052	951	1,751	1,726

* Short tons of 2,000 pounds each.

Kiukiang and Swatow are the original points of export of two-thirds of the entire amount of grass cloth exported from China, Chungking and Shanghai making a distant third and fourth. Two-thirds of the grass cloth

exported from all China is sent to Hankow, Chinkiang and Shanghai, where it supplies the re-export trade and the demand for local consumption.

THE ARGENTINE WHALE AND SEAL OIL INDUSTRY.

The seas of the south and east of Patagonia abound with whales, but very little attention has been given by the Argentinians to the whaling industry. However, there is one Argentine company with a whaling post in South Georgia Island, which is about 1,600 miles to the southeast of Buenos Aires, and about 900 miles to the east of the Falkland Islands. The company has four whaling ships of about 80 tons each operating at the island, and one sailing vessel engaged in the transportation of oil and fertilizer to England. Two more whalers were ordered in Norway for delivery in time for the 1921-22 season. The capital of the company is entirely Argentine; the manager is a Norwegian, and the technical personnel is largely Scandinavian. This company has been operating since the year 1904.

South Georgia Island is in the direct track of the whales coming from the Antarctic Ocean in their migration to the north during the mating season. In the month of November the whales begin to move past the island toward the African coast and across the Atlantic to a point between Brazil and north-west Africa, where the young are born. In their return the whales begin to pass Georgia in February and March. No whaling is carried on at the island from June until October because of the violent winter storms.

It appears from a report by the United States Trade Commissioner at Buenos Aires, that the Argentine whaling company operates entirely from the land, sending out the boats daily from Georgia to distances 40 to 50 miles from the island. The captured whales are brought back to the land. The company keeps a personnel varying from 200 to 1,000, and operates an extracting plant and crushing mill on the island. The annual production is from 25,000 to 30,000 barrels of whale oil and about 5,000 barrels of seal oil, although the production in 1920 was only approximately 20,000 barrels of whale and 2,300 barrels of seal oil. This decrease was due to a strike, and to the restriction of seal fishing by the Government of the Falkland Islands. (These seals are not of the fur-skin variety.)

The company disposes of from 8,000 to 10,000 barrels of oil in Argentine for local consumption, and exports the remainder directly to England in its own one sailing ship. Five classes of whale-oil and two grades of seal oil are produced. Only recently has this company begun actively to produce fertilizer, and the expectations are that the plant will produce 3,000 metric tons of ground fertilizer per year.

THE NATURAL RESOURCES OF SLOVAKIA.

Slovakia is a land of forests, mountains, and streams, about which comparatively little was known before the war. The total area of this part of Czechoslovakia is 25,000 square miles, of which 35 per cent is covered with forests of beech and oak. Every year timber is exported in large quantities. Connected with the lumber industry is the manufacture of toys. Toys of original designs and bright colours are a speciality of Slovakia, where they constitute one of the principal home industries carried on by the peasants.

According to a report by the United States Consul at Prague, the mineral resources of Slovakia have hardly been touched. During the war a new coal field with an estimated reserve of 124,000,000 tons was discovered in the neighbourhood of Nitra, and is now turning out coal to the value of 8,000,000 crowns per annum. Iron to the value of 40,000,000 crowns is produced annually by the mines of Dobsina; and to the north of Bratislava petroleum has been discovered. Gold, silver, and other precious metals are also mined, in addition to large quantities of antimony, magnesium, copper, mercury, and salts.

No list of the natural riches of Slovakia would be complete without special mention of the numerous springs of mineral water, which make the watering places of Slovakia the rivals of those in Bohemia. There are 30 thermal stations in Slovakia, the most famous of which are Tatranska Lomnica, Strbske Pleso, and Smokovec. The natural waters found at these places contain iron, sulphur, and iodine, in proportions which make them particularly effective for the treatment of nervous complaints, rheumatism, gout, anaemia, etc.

DEVELOPMENT OF POTASH DEPOSITS IN CATALONIA.

Preparations are under way for the exploitation on a large scale of the potash deposits near Suria, in the Province of Lerida, according to a report by the United States Vice-Consul at Barcelona. A Belgian concern is now building an immense plant at Suria, which it is said will have a production capacity more than equal to the total Spanish consumption. To facilitate the transportation of the potash, a railway to Manresa has been constructed, and plans have been completed to extend this line to the port of Barcelona.

The product of the Minas de Potasa de Suria is already being placed on the market, and it is thought that Spain will soon cease to import fertilizers of any kind if production in Lerida is increased as expected. Experts declare that the potash deposits of central Catalonia contain many millions of tons of this mineral.

Agriculture in Spain will be given a great impetus by the development of these deposits.

Journal of the Royal Society of Arts.

No. 3,636.

VOL. LXX.

FRIDAY, JULY 28, 1922.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C. (2)

NOTICE.

EXAMINATIONS.

The results of the Stage I. (Elementary) Examinations, which were held from March 31st to April 12th, were sent to the centres concerned on July 4th. Those of the Advanced and Intermediate Stages were issued on May 29th and June 12th, respectively.

The total number of papers worked in all three stages was 20,973, an increase of 5,289 on the corresponding examination of 1921.

In the Advanced Stage 2,371 papers were worked: 276 First Class certificates were awarded; the Second Class certificates numbered 1,094, while 1,001 papers were classed as failures.

In the Intermediate Stage the number of papers worked was 5,903, made up of 916 First Class and 3,361 Second Class certificates, and 1,626 failures.

Of the 12,699 candidates in the Elementary Stage, 8,629 passed and 4,070 failed. It is hoped to publish the results of the May examinations shortly; the Advanced Stage about the end of July; the Intermediate and Elementary Stages in August.

Two examinations will, as usual, be held in 1923. The first will begin on March 16th and finish on March 28th, the second will be held from May 7th to 17th. The time table has been sent to the Centres.

PROCEEDINGS OF THE SOCIETY.

TWENTY-FOURTH ORDINARY MEETING.

WEDNESDAY, MAY 31ST, 1922.

SIR CHARLES JOHN HOLMES (Director of the National Gallery) in the Chair.

The paper read was:—

THE PROBLEM OF PROVINCIAL GALLERIES AND ART MUSEUMS, WITH SPECIAL REFERENCE TO MANCHESTER.

By LAWRENCE HAWARD, M.A.,
Curator of the City Art Gallery, Manchester.

The subject of the paper which I am to give you this afternoon is "The Problem of Provincial Galleries and Art Museums, with Special Reference to Manchester."

Your Secretary originally invited me to talk to you about the Manchester Corporation Art Gallery, and to illustrate what I had to say by a series of lantern slides. This I readily agreed to do. At the same time I suggested to him that it might be of more interest to a general audience like this if, instead of confining myself to Manchester, I should treat the Gallery in that town as one of a number of provincial institutions, each of which is attempting, with varying degrees of success, to play some part in the artistic and educational life of the community surrounding it. In this way I hope to be able to present to your view, in some sort of perspective, the main aspects of the work that is being carried out, year by year, as part of the normal municipal programme of the city; and whilst doing so, I propose to touch incidentally upon certain problems connected with the nature, growth, and administration of public galleries, upon the right solution of which depends, as it seems to me, not merely the success of any particular institution, but the general well-being of the art of the country.

For it is often forgotten, I think, in London—and here I speak myself as a Londoner—that metropolitan art does not represent the art of the whole of England. The metropolis sooner or later, no doubt, attracts to itself the ablest of the younger men from the country. On the other hand, many not insignificant painters and art workers have refused to migrate to the

capital, preferring to remain provincial in the intensive sense of the word, and gather strength, like Antæus, from their native soil. How far this is to the advantage of all concerned—how far the desire of the moth for the star is good for the moths or the Milky Way—is an interesting and even a practical question; but to attempt to answer it here would take me too far from the more immediate subject matter of this paper. In any case, we shall all, I suppose, agree that whatever the case of a few individual artists may be, and in spite of such means of contact as occasional exhibitions may afford, London and the provinces know little enough of each other.

Londoners, taken as a whole, I think it is no exaggeration to say, are ignorant of the existence of many of the provincial museums and in the case of the larger and more famous galleries are—shall we put it?—somewhat vague as to their contents. And yet it is a common experience of those who are in charge of these institutions to receive enquiries as to particular works from America and the Continent, and to find visitors in the gallery who have travelled from distant parts of the country with the sole purpose of spending their time in seeing the collections.

It is not as if all these galleries and museums lay off the beaten track. Some are easily accessible from the more famous of our Cathedral towns, whilst others are to be found within a stone's throw of popular holiday districts. But those in search of health seldom have time to look for anything else; and even abroad, where English travellers are more deliberately conscientious in seeing the sights of the towns through which they pass, how many of those who have to change at Bâle think of inspecting the Holbeins in the museum, after they have sampled the delights of the Baths and the Buffet de la Gare? How many, even of those whose education has taught them something of the beauty of fine buildings, are aware of the pictures as well as the churches of Rouen, or of the mural paintings by Puvis de Chavannes at Amiens, which lie almost within the shadow of the great Cathedral?

Whether in this country or abroad the traveller must of course learn to take his chance. He must know beforehand what, as Henry James used to say, he is in for. Baedeker and the Blue Guides between them are fairly safe so far as the bigger fry are

concerned, but many interesting if unambitious minnows escape the meshes of their nets. In fact even the experts are sometimes being taken by surprise and are discovering treasures hidden amongst the cobwebs of some obscure or moribund museum. For some alas are moribund; some indeed are justly dead already; others are only sleeping with the semblance of death, like the flies upon the walls; some are dragging dead weights that hamper active movement; a few even are going through the laborious processes of creation, subject to the usual handicaps of the new-born infant. The majority are very much alive, though in some cases their vitality is largely spent in fighting various forms of ignorance and prejudice.

If we leave out for the moment all the weaker specimens covered by this summary diagnosis, and consider only a few of those that show unmistakable signs of life and are established on a secure basis, we can take note, up and down the country, of a number of works of art which are of interest and importance, not only to the general public but also to the historian, the student, and the connoisseur.

The paintings of the Venetian School and the Turner drawings at the Fitzwilliam; the drawings of Old Masters at the Ashmolean; the Burne Jones drawings and works of the Pre-Raphaelite School at Birmingham; the paintings by old Masters at Edinburgh and in the Roscoe collection at Liverpool; the old Masters and works of the Barbizon School at Glasgow; the examples of the Norwich School at Norwich; the Wilson's, Millais's and Madox Brown's at Manchester; the English glass and silver in the same Gallery; the historical collection of local pottery at Burslem and at Leeds; the Wrights at Derby; the Miniatures at Bath; and the representative examples of English painting of the last hundred years at Bradford, Newcastle, Dublin, Aberdeen, and other galleries already mentioned—all these are at least noteworthy, and many items would hold their own if shown with the National Collections in London. I have only picked out a handful of cases that occur to me most readily, in order not to worry you by multiplying instances to prove a case which should be obvious, but, like many other things that lie in the way, is often overlooked till pointed out.

There is of course another side to this attractive view of the treasure houses of provincial England. In many of them you will find the main galleries, to say nothing of the corridors and storerooms, blocked with certain ancient leviathans that uncoil their lengths upon the walls in the guise of battlefields, shipwrecked mariners, lighthouses, destructions of Sodom and Pompeii, and so forth. So overpowering are they that it almost seems as though the gallery must have been built up round them, or as if peradventure they had begun life as modest 50 by 40's, and then in that hothouse atmosphere that every gallery generates had grown to life-size scale. Another curious corner of provincial museums may sometimes be found to be adorned with the earlier masterpieces purchased out of Sir Francis Chantrey's notorious Bequest—works which my friends Mr. MacColl and Mr. Aitken brought themselves to the point of doing without, and have allowed ever since to remain a charge upon their generosity.

And apart from picture galleries, a number of institutions still survive in various parts of the country in which armour, pottery, savage weapons, electrotype coins, wood engravings, Indian mats and casts from the antique jostle each other and fight for precedence with samples from a dozen other byways of human knowledge—institutions which I ventured once elsewhere to say are "graced with the courtesy title of museums and are in reality little more than glorified curiosity shops."

These two types moreover—the treasure house and the curiosity shop—are not always entirely distinct. You will often find even in the best of the former some favourites of a previous day banished by a wise directorate to the packing-cases in the cellars—Pandora-boxes from which even hope has managed to escape; and in the darkest of the curiosity shops it is not unusual, as I have said, to light upon some neglected blossom in the dust, some tiny jewel shedding lustre upon its dingy and indifferent companions.

When we begin to enquire into the reasons for the existence under the same roof of a promiscuous jumble of good and bad, the presence side by side of method and disorder, we shall generally find that it is due to the combination of a number of circumstances. I now propose to deal with a few of these, in order to illustrate the

kind of difficulties that prevail in the organisation of provincial museums, and the way in which some of them have been solved in Manchester.

Many galleries start with a handicap from the very beginning. Some wealthy citizen with an omnivorous taste for the arts amasses a big collection of miscellaneous objects, and with a fine public-spirited gesture bequeathes them to his native town. The town council, partly in the glow of righteous possession, partly to avoid seeming ungracious by picking and choosing, and perhaps, too, by way of encouraging others to go and do likewise, accept the gift en bloc, and what was confusion in the private house becomes worse confounded in the public gallery. Sometimes the house itself is converted into a public gallery—the Louvre, the Zwinger at Dresden, and the Vatican galleries, to name three examples on a large scale, were all originally private palaces—with the result that even when there is no overcrowding the lighting conditions are frequently bad and the rooms unsuitable for the circulation of crowds of visitors.

The same unwillingness to hurt other people's feelings, combined, to some extent no doubt, with the natural joy of acquisition, is generally responsible for the acceptance of gifts which if offered as purchases would be more closely scrutinized; and purchases themselves may often be made in the artificial heat of momentary emotion, by a committee acting under the influence of what the psychologists call "herd-suggestion", with funds drawn from the gate money taken at a popular exhibition.

In fact the whole problem of purchasing with the various issues it connotes—the question as to what types of work it is desirable to acquire, where such desiderata are most likely to be found, whose business it is to decide whether a work is or is not of the required type, and, if it is, whether it is a good enough specimen of that type—all this has usually received little attention from those on whom the responsibility ultimately rests of spending public money to the best advantage. Even when a satisfactory pragmatic system of purchase has been hit upon, in nine cases out of ten there is little space available for displaying recent acquisitions. In many towns, moreover, the powers that be have ordained that an art gallery, a science museum, and a library (all three often controlled by

the same individual), are to elbow each other within the same four walls, art and science usually sharing the honours of the upper story, whilst books are relegated to the cellars; so that even when the visitor has run the gauntlet of the newspaper files and the card catalogue he is in delightful uncertainty whether on turning the corner in the corridors upstairs he is likely to be confronted with Staffordshire pots, stuffed birds, or portraits in oil of the leading local celebrities.

Nevertheless, these and other difficulties that waylay the steps of those who have to administer public galleries and art museums are not by any means insurmountable. Each gallery, in point of fact, seems to find itself able to tackle successfully some of the problems of good organisation even if others have to be left untouched. What is wanting is some general agreement as to first principles, some common understanding on the part of those most nearly concerned, to enable the different units all over the county, whatever their particular aims, at least to be animated with the same ideals.

Manchester is, I think, fortunate in many respects in having been able through a variety of causes to advance along a more or less definite pre-determined line, as the result of which she has forced circumstances to give way to her instead of allowing them to be one of her conquerors. And here let me say in parenthesis that if I quote what has been done in Manchester rather than in other centres, it is not because I wish to make invidious distinctions between equals; still less do I suggest that what Manchester thinks to-day has not been thought of yesterday, or even a week ago, by all her intellectual rivals. It is simply that I happen for obvious reasons to be better acquainted with conditions there than elsewhere and because it was, after all, of Manchester that your Secretary asked me to talk to you.

When I said just now that the Manchester Gallery had moved on fairly definite pre-determined lines, I did not so much mean that its policy to-day is the policy that was laid down at its foundation a hundred years ago, as that the aims of the group of men who first interested themselves in establishing a gallery in Manchester have been constantly borne in mind throughout its history whatever modifications of principle or detail may from time to time have been introduced. The Gallery itself, a charmingly

proportioned classical building designed by Barry, was originally one of those institutions for the promotion of the Arts, Literature, and Science, so many of which a few years later sprang up under the auspices of the cultural twins *Kunst und Wissenschaft*, in the days when good Prince Albert stood behind the throne. Science, however, soon became less prominent than the Arts in the Institution's programme, presumably because of the existence of purely scientific bodies in the town, and was eventually dropped entirely; so that when in the eighties the Governors decided to offer the building with all its contents to the city, it was no miscellany of art and natural science that the town inherited, but a collection of reputable pictures, together with a tradition of supporting the fine arts by holding periodical exhibitions, lending rooms to the local Academy of Painting for teaching purposes, and showing the citizens examples of good current art obtained by purchase and by loan. When the Institution was transferred to the Corporation and maintained out of the city rates, one condition was imposed by the Governors, namely, that for a period of twenty years the sum of £2,000 should be spent annually in the acquisition of works of art. The condition was, of course, accepted and on the expiration of the term agreed upon the same sum was voted year after year by the City Council, and has been continued with a brief voluntary break during the war until to-day. The money, I should add, does not fall into the common fund, but accumulates, if it is not exhausted at the end of the financial year.

To the works which have been gradually acquired by purchase have been added a number of most generous gifts and bequests, which would have been more numerous still but for the inadequate accommodation that the present Gallery offers. Local collectors, as is now known, have refrained from leaving to the city treasures which ran the risk of being stored away out of sight, or of being shown under such crowded conditions that they could not be properly seen. More than one collector has indeed made his bequest conditional on a new Gallery being built within so many years, in the hope of thus stimulating public opinion. Others have shown themselves more simply generous, and through them the town has been enriched

with good collections of English Pottery, glass and silver, Chinese and European porcelain, and mezzotints besides, of course, paintings and early English water colours. These watercolours are not only very choice in quality; they also cover the whole range of the art from the early topographical draughtsmen down to those who are living to-day. Indeed the watercolours belonging to the Corporation taken with those at the Whitworth Institute (a public Gallery administered by Trustees), make Manchester richer in the English School than any town in the kingdom except London.

These and other gifts to the city have brought about a state of congestion in the Gallery that renders it absolutely imperative that new quarters should be found. At present there is no way of showing the glass, silver, and porcelain, except by filling up the floor space of the Gallery with cases which have to be crowded together and prevent the visitor from obtaining a general view of the pictures on the walls behind. But for the war these new quarters might already have been provided. As it is, the City Council has decided that on the large site in the centre of the town where the Infirmary once stood, a new building shall be erected in which provision will be made for housing not only the fine, but the applied arts, and those examples of modern textiles, ceramics, wood and metal work which demonstrate the application of good design and workmanship to the articles of everyday life.

The only possible advantage of having an over-crowded Gallery such as ours, that I can think of, is that every fresh acquisition involves moving something else in order to give it a place. (The advantage is, you perceive, not peculiar to the conditions). To move an exhibit, especially if it is a popular one is, I am convinced, a good thing to do. If the public never sees anything but the old familiar faces exactly where it is expecting to find them, it soon begins to take them for granted and eventually fails to notice them at all. Even when it is not necessary to make way for fresh acquisitions, the permanent collection should, if only on these grounds, be rearranged from time to time within, of course, reasonable limits. For the same reason the holding of temporary exhibitions; though it may involve dismantling a portion of the collection, is to be advocated as

providing a stimulus quite apart from that of the Exhibition itself.

During the last ten years, as many as sixty exhibitions of one sort or another—paintings, drawings, etchings, Chinese porcelain, modern domestic pottery, textiles, cottage furniture, printing, theatrical designs, American architecture, and so forth—have been held in the Manchester Gallery; and we were recently responsible for a demonstration of what can be done to-day in the way of cheap and simple furnishing, which was carried out in one of the new Corporation houses in conjunction with the Housing Authorities and the local branch of the Design and Industries Association. This demonstration was seen by nearly 30,000 visitors, and during the ordinary exhibitions in the Gallery the average daily attendance is over a thousand. These figures are, I think, proof enough that a series of exhibitions will repay the time, trouble and money spent upon them, in the number of people that they attract to the Gallery; and it is noticeable that those who have once been interested in a particular exhibition, and have come to the Gallery for the first time, perhaps, to see something they have been told will appeal to them (it is often something relating to local conditions or requirements) will come back again in the expectation of finding more things likely to prove attractive. In other words, once establish a live policy within the walls of the Gallery, and you have secured your public, which not only consists of an aggregate of casual visitors, but constitutes the soil in which are nurtured students, artists, craftsmen, and even potential benefactors.

Exhibitions such as those I have described, should not, I think, be left to speak entirely for themselves. Apart from the publicity gained by dignified and clearly printed posters, it is advisable to issue small catalogues and leaflets describing their main features and sell them, not with a view to making a profit for the Gallery, but at a price which will just cover the cost of production; and it is often good policy to arrange for special lectures to be given in connection with some temporary exhibit, whether of works on loan or of those from the permanent collection. A recent lecture, for example, by Mr. Hobson, of the British Museum, on jade, on the occasion of a loan to the Manchester Gallery of a choice collection from a local collector, and another on

Mezzotint, from Sir Frank Short, during the exhibition of a large bequest of examples of the English engravers of the 18th century, drew very large audiences, and from the stimulus that was thus given to collectors and enthusiasts (who were brought into contact with the lecturers and could follow up their points by studying the objects in the exhibition, that illustrated them), had a wider and more permanent influence than if they had been given casually apart from their context.

Numerous lectures on various subjects connected with art are given in Manchester during the course of the winter months, not only at the Central Gallery, but also at two of the Branch Galleries that are situated in populous districts, and a very large and varied collection of lantern slides of paintings, statuary, engraving, architecture, and so forth, is at the disposal of any accredited borrower. Arrangements are, of course, also made for conducting parties of visitors round the Gallery, usually after a preliminary talk has been given on the scope of the collection, and a few hints as to how to look at pictures.

A more purely educational piece of work has also been carried out in conjunction with the Manchester Education Committee. Owing largely to measures which were adopted in war time, to find occupation for the children whose school buildings had been converted into military hospitals, and who had, therefore, to share a building with another school, some 600 children a day are now given very elementary talks on the contents of the principal galleries and museums in Manchester, by teachers specially trained and appointed for that purpose. In this way the young people (the citizens to be) learn from an early age to regard a visit to a Gallery as a perfectly normal experience, and very soon they not only enjoy coming themselves, but they return in their leisure hours with their friends and parents.

The accessibility, for purposes of study, of objects in the collection which are not actually on exhibition, is a problem which the lack of space, that I have already referred to, has made it very difficult for us to solve. It is no consolation to think that even at the Victoria and Albert Museum there are practically no study rooms for research work, and that in the British Museum the Reading Rooms and Print Room have nothing corresponding in other

departments. In preparing the designs for the National Museum of Wales at Cardiff, which is now in process of being built, the provision of Study and Storerooms was carefully taken into consideration and the examples set by this great Institution will, it is to be hoped, be followed by all who are in the fortunate position of looking to the future for their museum, and not to the past.

Another first principle in museum organisation, on which one would expect common action as well as common agreement on the part of everyone concerned, is the necessity for setting out all the exhibits in a way calculated to show them to the very best advantage. I do not propose to speak of technical device of arrangement, lighting, and so forth. I only wish in a general way to emphasize the fact that many provincial museums are at a great disadvantage from the nature of the rooms provided, which even when the museum has not been adapted from a palace or a private house, are constantly too dark and too large. Nothing is so depressing, so lowering to the vitality of a good picture, as a dark room or one which overwhelms the canvases with a vast expanse of wall running up through frowning cornices to the stately pleasure-dome the architect so thoughtlessly decreed. One of the most needed, and, if I may be allowed to say so, one of the most successful reforms that our distinguished Chairman has carried through at the National Gallery has been the brightening of the walls and the apparent lowering of their height by the most skilful use of the office paint brush, and by what might be roughly described as architectural camouflage.

In point of fact, the various devices we have been considering for overcoming the numerous difficulties of organisation with which galleries and museums are confronted are based on two fundamental axioms: "Show things to the best advantage," and "Have only the best to show." With the first of these I have already dealt. It only remains for me to treat very briefly the problem of high standards which it is the primary duty of all who are directly or indirectly connected with the Gallery consistently to maintain.

The simplest plan of all for showing only the best in the Gallery is to withdraw from exhibition everything which does not reach a certain standard. This may be a little

drastic for some institutions, but I know of no better way. Works of art are like human beings: they are affected by the tone of the company they keep. Fine work in mediocre surroundings, so far from shining all the brighter by contrast, will almost seem to sink to the level of the second-rate, or whatever their lowest common multiple may be.

Purchases I will come to in a moment. As to gifts, the task of refusing those that are poor in quality is not in reality so difficult as it may appear. A good deal depends on the donor and nearly everything on the way in which the matter is handled; but it must be rare, I think, for a director to find a would-be donor so impervious to reason as not, sooner or later, to be brought to share the view that when a gift is accepted by a public gallery the donor is often honoured at least as much as the institution.

It is a more difficult matter in most galleries to maintain the same high standard in the purchases, because, whereas the scrutiny of gifts is often left to one individual, it is very rare to find decisions as to purchases not made by an entire Committee. Now, Committees, I suppose, have their purpose in this teleological world, and may even function well, especially when the constituent members of it refrain from attending meetings. In the matter of purchases, the function of a Committee should be to decide such questions as whether any money is to be spent on buying works of art at all, what type of work it is desirable to add to the collection, what should be the maximum spent at one time, and so on; its business, that is to say, is to decide matters of general policy. But a decision as to any specific work, more particularly a decision as to the relative merits of several different works, requiring, as it does, expert knowledge and taste, should never be made a matter of collective judgment, with its inevitable corollary of divided responsibility. Even in the unlikely event of all the members of a Committee being trained judges,—*quot homines*—their taste will vary, and if they are intelligent and strong minded, they are bound to differ about works of primary importance, and will, indeed, often, only be able to come to an agreement about those that are not of sufficient interest either way to rouse their passions.

The individual may make mistakes; (Crichton himself, had occasional lapses);

but if his mistakes are rare they are more than compensated for by his sound judgment; if they are frequent, the remedy is to find another individual to take his place.

Even for the conduct of the general business that has to be transacted by a Gallery Committee composed of city councillors, it will, I think, often prove advantageous to co-opt a few independent advisers, chosen for their special knowledge or for their interest in particular sections of the collection. The constitution of the Committee may not always admit of this, but a way out may sometimes be found by the device of delegating different pieces of specific work to Sub-Committees, and then co-opting on to these smaller bodies members to act in what is quaintly known as an advisory capacity.

Local interest should, in fact, be used officially or unofficially, wherever it is required. The way in which workers in various special fields are ready in a place like Manchester to give their time and put their knowledge at the disposal of those who are ready to make use of it, is very striking, and, of course, by no means peculiar to Manchester. Another sign of the spirit of friendly co-operation prevailing there, is to be found in an agreement that has been arrived at by the various galleries and museums in the town to keep each other informed, by the machinery of occasional meetings, as to their respective lines of action and future development, with a view to preventing waste and overlapping in matters either of detail or of general policy. Quite recently, too, a Federation has been formed of the various local art societies which, it is hoped, may be able to influence public taste by bringing a body of united opinion to bear wherever it may be required.

Such co-operation as this amongst the purely local galleries, has a parallel in the relations between the National and the Provincial collections. If more has not been done to make the National Collections available to the nation, as distinct from the inhabitants of London, it is largely, I think, because the provincial galleries have not always realised how ungrudgingly those in authority in the great National Galleries and Museums will impart their knowledge and render assistance in a variety of ways to their provincial colleagues out of the abundance of their own treasures.

You will see from what I have said this

afternoon, that the task of administering the provincial galleries is both exacting, because of the difficulties with which many of them are contending (under conditions that in the smaller towns amount practically to spiritual isolation) and exciting, owing to the possibilities inherent in the spirit of local patriotism. The force of this local patriotism is not always, I think, quite appreciated by those who have never lived outside London. It is a very remarkable moral asset in the life of a community, both for good and, on occasions, for bad; and it is this force which makes it so much easier to get things done, as the phrase is, in the provinces, than in London. Londoners—and here again I speak as a Londoner myself—are nothing if not critical; in the provinces purely destructive criticism is regarded as waste of time, and the spirit of humorous toleration, born of cynical detachment, is not in the least appreciated. These gaps in the psychological outfit are, I think myself, a loss in the case of individuals, but a gain when you are dealing with people collectively. However that may be, there can be no doubt that there is a vast fund of idealism in the big provincial towns which is waiting to be turned to account, and which is the more easily accessible from the fact that it is localized and concentrated, the area to be covered being smaller than in London and the population in it less fluctuating and therefore more susceptible to repeated impressions.

This, in terms of the subject matter of our paper, means that provincial galleries and art museums scattered up and down the country, if only they know how to use their opportunities and are given a fair chance of putting their knowledge into practice, can become a really vital influence in the town, setting standards of reference for students, artists, and craftsmen, and acting generally as cultural centres for the whole community.

The slides I shall now proceed to show you of some of the more interesting of the treasures in the Manchester Gallery, would by themselves, I think, have been of little use as an illustration of the work that is being carried on there, and still less as an index to the potential influence of provincial galleries in general, without some such sketch as I have attempted to give you of what has been done in the past, and what it is hoped by the Municipal

Authorities to do in the future, to give art its rightful place in the daily life of the people who have to live in the huge commercial capital that lies at the very heart of industrial Lancashire.

DISCUSSION.

THE CHAIRMAN (SIR CHARLES HOLMES), in opening the discussion, thought Mr. Haward must be esteemed a lucky man because he was able to speak of provincial museums with an air of optimism, which he had always noticed accompanied success. He thought it was a great thing that an important Museum and Art Gallery like that of Manchester should be in the hands of an optimist, both for the reason he had mentioned, and also because optimism generally carried with it what might be termed a live policy. Museums and art galleries, whether provincial or metropolitan, were perfectly useless unless they were alive, and he was very glad to think that the policy of recent years, which owed so much to the advocacy of Lord Sudeley, particularly the establishment of lectureships in various museums, had not only been generally adopted, but had proved that Lord Sudeley was perfectly right in the interest it had aroused. He was specially pleased that Mr. Haward had mentioned that lectures were a part of the regular curriculum of Manchester, because he was sure that the establishment of lectureships was the means by which any provincial corporation and any metropolitan body would obtain the best use from their museums; indeed, it was only by those means that they would obtain full use of their collections. Mr. Haward had also pointed out that museums, if intelligently handled by means of lectures and so forth, became nuclei of culture and education, and that visitors who were attracted perhaps once by a lecture brought other visitors in their train. He need hardly say that the benefits visitors derived were not limited merely to the study of the objects the museum contained or the immediate impression that the visitors derived from them. What was far more important was that the people who came should be interested in something which had a permanent relation to history, whether of their own city or their own or any other country. At present we lived in a democracy, which was in perpetual danger from want of knowledge on the part of the voting population. He could not conceive any way in which the great democracies of this country could learn to administer the powers that lay in their hands half so well as if they went regularly, as a part of their regular education, to museums and galleries, and thus were brought into touch with the great achievements of the past, so that they recognised that they were not merely dwellers in this or that village or city, but were part of a universal citizenship which had

a history of many thousand years. If thereby even only a small proportion of them learned something of the history of the past they would be a great deal better able to deal with the affairs of the day than he often feared, sometimes after attending debates in the House of Commons, was the case at the present time. He was very glad to see that side of museums was one on which the author placed great emphasis. It had been developed recently in London to a considerable extent, but he would like to see it a regular feature in a great many provincial museums, too. He did not think, however, a live policy of that kind would be adopted in a great many provincial centres until provincial municipalities recognised that the headship of their museums and galleries was a post which deserved the most careful consideration and selection. During the last ten years, since he had been in London officially, he had often been consulted informally with regard to provincial appointments, and in some cases he had been shocked by the views that men important in their own places appeared to take of those positions. The decisions in one or two cases known to him were nothing short of deplorable. The idea that an important gallery in a great industrial centre could be managed by some employee of the corporation, who had hitherto been assistant librarian and who had perhaps married the daughter of a town councillor, was a great deal too common, and until members of provincial corporations recognised that they possessed in their museums institutions which in their way had almost as great an educational function, and might be almost as great a credit to the city in which they existed as their universities, the grants that they gave were in great danger of being wasted, and museums would remain in the condition to which the author had referred. There was another point of view, from which it appeared to him that provincial corporations were short-sighted. The author had referred, very rightly, to the necessity of maintaining a high standard of exhibits. It was well known that when a gallery had a reputation for having a low standard of exhibits nobody thought of going near it unless fate left them at the station with two hours to wait. On the other hand, a museum in which a high standard had been maintained was an institution which not only all connected with the subject in this country were obliged to visit, but that students even from the Continent had to visit if they were making a special study of any particular subject. Bearing in mind the standard of a good many Continental collections, it would be recognised what an asset they were to the cities which contained them. It was felt to be a mistake if a place was not visited which had a famous gallery or a famous museum. That was the sort of feeling he would like people in this country to have in connection with provincial museums, and it was a great pleasure to him to know that

there were present at the meeting two men at least who were identified with collections of that quality. But collections of that quality would never be obtained unless great care was exercised in the choice of the director. If that care was exercised, the director gained the confidence of the municipality with which he had to deal, and in a very few years was able, or ought to be able, to do what he pleased with his committee, so that when he wanted an important thing for his museum he was able to get it at once. The difference in salary between a good man and a cheap man was repaid ten times over to the city if it would take the trouble to get a good director. Lastly, in connection with the need of high standards, he desired to make a few remarks with reference to that depletion of the art treasures of the country which was occupying so much of their thoughts at the present time. It had often occurred to him that in cases in which the starved metropolitan museums could not intervene to save some of the masterpieces that were going out of the country, there were, in provincial centres here and there, men who, if they liked, could "plank down" the price and not feel it very seriously. He looked forward to the day when one or two of the fortunately directed provincial centres would relieve institutions like his own from the discredit which attached to it when from time to time first-class masterpieces, which ought not to leave the country, did so. He did not see why some of the provincial galleries should not, under the best guidance, do even better than they had done in the past. Since space even with them was always a consideration, it was a very much better policy for them to secure ten first-class masterpieces than 100 paintings which were just short of being masterpieces. They took up much less room, and the ordinary admirer of paintings and art had to stop at that town and visit the gallery, whereas he would not do so to look at 100 second-class paintings. In that way the credit of the collection, and he believed in time the reputation and income of the city, would be increased.

SIR WHITWORTH WALLIS (Director, Corporation Museum and Art Gallery, Birmingham), said he desired to endorse what the author had said with regard to the important question facing most provincial museums in regard to the appointment of suitable directors. During his 37 years' experience in the provinces there was hardly a provincial gallery or museum in England, Scotland or Ireland that he had not visited at different times, and if these museums were to become the great educational asset they should be a very different type of director or curator would have to be appointed from those who had occupied the position in the past. It was necessary to have men of far broader views, with far more knowledge of art, greater general culture, proper art training both at

home and abroad, than some of the men who were appointed at present. Sir William Flower, the Director of the Natural History Museum, stated in his presidential address to the British Association many years ago, that the life of the curator was the life of the museum, and that the life of the museum was the life of the curator; and that no museum would ever be a great success in this country unless the curator or director occupied more or less the position of dictator, one who would not be always guided by the fancies and the likes and dislikes of different members of the governing body. There was no committee like a committee of one, that one occupying the position of chairman, and he was a great believer in that policy. He also believed that if the curator of an art gallery once obtained the confidence of his committee they would accord to him a very considerable measure of dictatorship. Another important point was that so many of the museums in the country had no definite policy; they were a mere *omnium gatherum* of popular pictures—popular pictures of which the public tired, and no use whatever to the art student or collector. He visited one such museum on the seaboard some time ago, and could not help remarking that if they went on collecting pictures long enough they would have to roof in the whole city! In his opinion it was desirable in provincial museums more or less to specialise. Certainly in great cities like Liverpool, Manchester and Birmingham the museum should have a *raison d'être*, and if they specialised they would draw the public from a distance. They would come to see, he would not say ten masterpieces, but they would come to visit collections formed with a definite purpose. He hoped he would not be thought conceited if he mentioned his own gallery, which he was appointed to when the collection was housed in a small gallery at the Free Library. The present buildings now contained seventeen picture galleries, a great Industrial and Decorative Art Museum, bearing upon the industries of the City and district, a Museum of Classical Casts, and a Natural History Department. Towards the new buildings one Birmingham citizen bequeathed £50,000. Birmingham made up its mind to specialise, and with all due deference to the Tate Gallery and other galleries, he advised those who wished to study English pre-Raphaelite art to go to Birmingham for that purpose. Americans not only visited the town in which he resided, Stratford-on-Avon, but they also visited Birmingham to see the most complete collection of pre-Raphaelite pictures and drawings, the early Millais's, the Ford Maddox Brown's and the Rosetti's, together with the most important collections of works by Birmingham's sons, David Cox and Burne Jones. Definite collections acted as a magnet. They not only attracted visitors, they also induced gifts from people interested in certain phases of art. The whole of the

collections at Birmingham, valued at £300,000, had been presented, and had never cost the ratepayers a penny, except for the upkeep of the buildings. During the last 35 years, Birmingham had received in that way, gifts worth many thousands of pounds from people in no way associated with Birmingham, who were simply collectors of similar works by artists whom they wished to be represented in the gallery. With regard to the question of the buying or accepting of works of art, he would like to see inscribed over the room of every curator of an art gallery: "It is not what you accept that will make your art gallery; it is what you have the courage to refuse."

Mr. J. BAILEY (late of Department of Circulation, Victoria and Albert Museum) said he desired to emphasise the point the author had mentioned in regard to the constitution of the Committees that dealt with Museums and Art Galleries. Ordinary Town Councils did not attach very much importance to the Museum Committee. Generally, if a man was newly elected to the Council he was put on the Museum Committee, because he was not looked upon as being a sufficiently good man to deal with drains and things of importance. If, as sometimes happened, the Museum was placed under the Parks and Cemeteries Committees, all hope might be abandoned! The average Town Councillor was not the sort of man to deal with Museums, and he could say that with the more knowledge because he happened to be a Town Councillor himself. Members were frequently selected for the various Town Council Committees because of the qualifications they did not possess. In his own particular case, after doing 45 years of educational, including Museum, work, he was appointed a Member of the Committee dealing with the diseases of animals. It was necessary that that state of affairs should be rectified if progress was to be made. He agreed with the author that the proper course to adopt was to elect a certain number of people from outside who really knew something about Museums and education. With regard to the choice of a Curator or Director, he remembered that the first Museum that he visited in his official capacity was in one of the lesser cathedral cities. He there saw a man washing the steps of the entrance, and enquired of him where he could find the Curator. The man said to him very proudly: "I am the Curator!" On asking the man to be kind enough to show him the arrangement of his collection, he looked at him as though he thought he was an idiot escaped from Bedlam, and then replied, "The arrangement of my collections?—I put 'em in places that fit 'em!" One could quite imagine what sort of *omnium gatherum* existed in that city, where, curiously enough, the Committee were composed for the most part of dignitaries of the church, who ought to have known better. The author had pointed out that the Metropolis

was not England. There was a great deal illustrating arts and crafts at the hub of the universe, and possibly not sufficient of it was getting to these industrial centres, which were more or less interested in those matters. Having been in charge of the circulation of collections at the Victoria and Albert Museum for some years, he could fully endorse what the author had said in that respect. He thought the time had come when the central institutions were getting almost more material than they could deal with, and that the smaller local ones were more or less starving. That state of affairs should be put right by means of co-ordination of effort between the various institutions which were lending in some form or other works of art to Provincial Museums. The Victoria and Albert Museum, the Natural History Museum, and the National Gallery, were rendering great assistance by lending some of their collections but it was not always the case that the curator who was placed in charge of those examples in provincial centres possessed that knowledge of the necessity of protecting them, for instance from sunlight, which he ought to have before being placed in charge of works of that character. In his opinion, the work of the Central National Institutions should be co-ordinated, and there should be one central Circulation Department dealing with all the Provincial Museums, keeping a general eye on them and assisting them upwards. Such an organisation would be in a position to give a Curator considerable leverage in rejecting unsuitable examples. He remembered when visiting one Museum at a sea-port town, seeing some wool pictures, and on enquiring from the Curator why he kept such things, he was told that they were given by a Town Councillor! There was still room for improvement, and for really great assistance from the centre to the outlying Museums, and he hoped that in the near future some co-ordinated scheme would be adopted which would enable them to give that further assistance which the local Museums required.

PROFESSOR ARTHUR M. HIND (Slade Professor of Fine Art, University of Oxford), said that at Oxford he was faced by a very difficult problem, because there was no really serious study in the history of Modern Art, except in music. An attempt was being made to introduce some definite study of the subject as part of a degree course. That appeared to him to be of very much greater importance than trying to establish a large and ambitious school of art, because the aim of a University should be essentially humanistic. Subjects like engineering having been introduced, it was perhaps inevitable in the end that a practical study of architecture and other arts should follow, but he did not think that this should be the first aim of a University. It was his desire to see a study of particular portions of the

history of art—for instance, the history of Renaissance art and outlines of the History of Architecture—introduced into the History School. Difficulties would be involved, as probably the great majority of the Board of the History Faculty at Oxford would be against innovation, the argument being used that such subjects were entirely different from the special subjects that had hitherto been taken. The question of improving the status of Keepers of Provincial Galleries was linked very closely with the problem, and was of great importance from the point of view of art education in general. It was probably from the Universities that the men most suited for those positions would be obtained. If the proposals were adopted, such men might be advised to take a History Course, together with some special subject in the study of Modern Art. But it would hamper the possibilities of such courses if the men knew that there were no appointments open to them afterwards, in connection with the study they had gone through. Personally, he would be glad to hear the opinion of Provincial Directors on the subject of the possibility of the Universities helping in connection with the education of men for the positions they occupied. It was also exceedingly important in his opinion, that greater co-ordination between the British Museum, the Victoria and Albert Museum and other bodies of that kind should be inaugurated. There had always been a feeling, so far as the Provinces were concerned, that they should be generous to contemporary art and try and buy the works of living painters. On the whole, he thought that was more a matter for private purchasers, and that the important point in the making of a Provincial Gallery, as in a national collection, was to keep up the right standard of works of art. When it was impossible to obtain masterpieces by great masters they should endeavour to obtain representative collections of engravings and drawings, because in that way the Provincial Museums could, in many cases, keep the right standard and at the same time keep within their means.

MR. ARTHUR SEVERN thought that in all provincial exhibitions a picture of a great event that had happened in or near the place ought to be well shown. He was disappointed to see, a year ago, in the beautiful Newcastle Gallery, a picture by John Charlton, depicting a lifeboat which had been brought for miles by 150 women, placed in a dark corner. In the case of such a picture, even if it was not a very good one, the people of the town ought to be able to see it properly.

MR. A. F. KENDRICK (Department of Textiles, Victoria and Albert Museum), said it seemed to him the author had gone a good way towards solving the problem of Provincial Museums, the outline he had given for their activities being an admirable one. It had to be borne

in mind, however, that the problem of Museums was insoluble by any generation. Nothing much could be learned of astronomy if it was possible to see only a few hundred thousand miles, and as Museums had to survey the intellectual activities of men from the beginning of time, their scope was too wide for any final solution. They could only adapt the problem as it appeared to them to the conditions of the day in which they lived, and to the locality which they served. It was impossible for all the Provincial Museums to do what Mr. Haward had done at Manchester, and the Chairman had done in Trafalgar Square. The Museum problem was one of compromise with the conditions of time and place, and each Director must do the best he could. When Mr. Bailey referred to the Curator whom he saw washing the steps, he thought Mr. Bailey was praising the Curator. He heard the other day, that when somebody went into the National Gallery he saw the Director white-washing the walls. He respected any Curator who would act in that way if the occasion called for it. The principal point he wished to make was that it was necessary for them to turn their hands, in the very unfortunate circumstances that existed in Museums at the present day, to adapting them to the times in which they lived.

MR. W. S. MARCHANT said that in the purchase of modern works Provincial Galleries were in competition, not only with the private collector, but also with the dealer, and if they were to attempt to obtain the finest works of the present day they must be in a position to secure them as against the dealer or private collector. It was part of his duty to receive occasional deputations from Provincial Galleries, and he noticed that one of the great difficulties experienced was the impossibility of obtaining unity in those purchasing Committees. One question which required study was the exact status of the Curator and of the Art Committee with which he was connected. He had never yet had experience of a Provincial Committee in which the Director was the dictator, and disputes most naturally arose where a number of people had to give their opinions. Some years ago he spoke to a prominent Member of the Contemporary Art Society on this question of buying, and told him that until they nominated a purchaser and gave him authority to buy just what he liked, up to a certain amount, they would never be able to compete in the market with the private collector or dealer. Apparently this system was afterwards adopted.

MRS. JAMES DUNCAN, after thanking the author for his paper, stated that she thought the most important point it emphasised was the necessity for co-ordination. In a big town like Manchester it would be desirable to have two Galleries, one containing the historical works of

great masters and another containing modern works. She suggested that the Gallery containing the modern works should not be a permanent one, but that travelling collections should be formed which could be sent round the country.

THE CHAIRMAN, in proposing a hearty vote of thanks to the author for his excellent paper, said he only desired to say that, to the best of his recollection, the story which had been mentioned about his having used a whitewash brush in public in the National Gallery, was apocryphal.

The resolution of thanks was carried unanimously, and the meeting terminated.

THE CZECHO-SLOVAK GLOVE INDUSTRY.

Before the World War, the glove industry in Austria-Hungary is said to have given employment to some 30,000 workers, and to have reached an annual average production of 1,500,000 dozen pairs, 80 per cent. of which were exported to other countries. Owing to the low price of raw materials, it is said that fully 50 per cent. of the profits remained in the country in the form of wages.

Although about 80 per cent. of the former Austrian glove factories came within the boundaries of Czechoslovakia when the new Republic declared its independence, near the close of 1918, glove production in Czechoslovakia has decreased 8 per cent. of what it was before the war.

According to a recent report by the United States Consul at Prague, the present unfavourable situation in the industry is said to be due to the difficulty of competing with Germany and Italy for foreign markets. In Germany the cost of labour is about 25 per cent. lower than in Czechoslovakia, and in Italy it is said to be even less. It naturally follows that German and Italian gloves of equal quality are in greater demand abroad.

The trade is further embarrassed by a shortage of skilled workers. In certain sections of Bohemia, the glove factories suffer from a lack of skilled labour to such an extent that hundreds of machines are no longer in operation and the pre-war production of 2,800 to 3,000 dozen pairs of gloves a week has dropped to about 200 or 250 dozen pairs.

The principal export districts for the glove industry in Czechoslovakia are Prague, embracing the cities of Tabor, Lyssa, and Tuskov; Rudohori, embracing Kadan, Abertany, Berinky, Jachymov, Blatno, Hroznetin and Wiesenthal; Brno and Losice in Moravia; and Fryvaldov in Silesia. These districts show many variations with respect to the manner of production and the kinds and qualities of gloves produced. Washable gloves are principally manufactured at Kadan, in the Rudohori district, and kid

gloves in the mountains. There is a considerable domestic consumption of kid gloves. In Prague the production is varied, a part of the output being finished at homes in Rudohori. Before the war, about 80 per cent. of the glove export trade was centred in the Prague district, the factories of which accounted for some 1,000,000 dozen pairs of the annual total production.

Of the total exports of leather gloves during 1921, amounting to 179,455 pounds, 112,640 pounds went to the United Kingdom, 18,260 pounds to Austria, 11,660 pounds to the Netherlands, 7,920 pounds to the United States, and smaller amounts to other countries.

PEPPER IN SARAWAK.*

Pepper growing, which used to be one of the chief industries of Sarawak, is gradually dying out chiefly on account of a disease for which no cure has yet been found.

It is grown on red loamy soil and will not flourish in clay or sand.

The Pepper vine was cultivated in the Upper Sarawak district and at Lundu and Simatan; these are the old plantations; large quantities are now grown in the Batang Lupar and Rejang districts, but the plantations are not sufficient to replace the large districts which have died out in the Upper Sarawak district.

The amount exported in 1911 was about 2,800 tons as compared with just over 1,000 tons in 1920.

PLANTATION.

There are two kinds of vines grown in Sarawak, the broad leaf vine and the small leaf vine.

Vines are planted from cuttings in soil prepared with burnt earth, in the months of August and September; the cuttings are planted 4 to 5 feet apart and they require shading until they begin to shoot.

When they have been planted about 8 months a belian post (tuat) about 16 feet long is put in the ground near the plants leaving some 12 feet above ground for the vines to grow around. Burnt earth is applied to the growing vine 3 times a year until it bears, which is about 2 years after planting; while the vine is maturing the flowers appearing on the growing shoots are plucked.

After two years' growth, when the vine is considered mature, flowers are left to seed but the young shoots are thinned out continually; the stronger shoots are tied to the post by means of a jungle twine made from "kulit sla-ut," at this period the vines are manured with pawn refuse (abok sessar), about 6 tahils being applied to each vine.

The crop is harvested about 10 months after flowering, in the months of July to September.

If the crop is weak quantities of berries drop to the ground; these are gathered up to be marketed as black pepper.

This is the more usual method of cultivating pepper at the present time; in the old days, however, the method of cultivation took longer, the method being as follows:—

When the shoots from the young plants had reached a height of about 6 feet up the post they were pulled down and curled around the foot of the post, three or four of these shoots were layered, the rest being cut off; these layered shoots being again thinned out as the vine grew up the post until the vine was considered mature, about 3 years after planting, when the flowers were left to seed.

Although by this method the vine did not come into bearing until 3 years after planting, it continued to bear heavier crops for some 20 years, as against 10 to 15 years by the present method.

To continue the description of the growth and care of the pepper vine: when vines approach the bearing season they are sprayed with a mixture of rotten tobacco and tuba, prepared with water; but even this spraying does not appear to prevent the spread of the fatal disease of black berries known amongst Chinese as "Voo Choon."

It is this disease which has done such damage to the gardens of Upper Sarawak district that the industry is dying out.

PREPARATION

White Pepper is produced from the plucked berries which are gathered during the harvest, packed in gunny bags and immersed in water for about one week or until the outer skin of the berries has rotted off.

After immersion the berries are put into baskets and washed, during the process the baskets are rotated by hand, when the rotted outer skin rubs off and is easily separated from the clean berries remaining.

The washed seeds are then sun dried, after which they are shaken up in large open baskets, the stalks being separated from the seeds during this winnowing process.

The dried seeds are now ready for the market; only 5% moisture is allowed to be contained in the finished product; this standard is maintained by Government regulations and Inspectors are appointed to control this.

Black Pepper.—There are three methods of preparing black pepper.

(1) The plucked berries are piled in heaps in the house of the planter where they are left for three days, after which they are sun dried for another three days.

(2) The plucked berries are poured into boiling water after which they are sun dried.

(3) The berries are smoked over a fire, being placed on mats made of small sticks and twigs until dry.

*Extracted from "Notes on Sarawak Trade," published by the Committee for Agricultural and Forest Exhibits, Malaya-Borneo Exhibition.

We have already noted that the dropped berries as well as those plucked are prepared for Black Pepper.

FINANCIAL ARRANGEMENTS.

In Sarawak, gardens are generally owned by the individual planter, who mortgages the crop to a merchant in return for provisions during the unproductive period; after the first crop is gathered the whole of which is delivered to the mortgagee and settlement of his account has been made, he applies for an advance on the forthcoming crop; this is usually given partly in cash and partly in provisions.

The merchant sends his agent to examine the applicant's garden who estimates the quantity of the forthcoming crop and reports to the merchant who allows the planter up to 60% of the estimated value of the crop.

This system continues and advances are given against the forthcoming crop annually.

The pepper gardens in Upper Sarawak are rapidly dying out, but it is being planted in the 2nd and 3rd Divisions of Sarawak. The crops from these newly planted districts are superior in quality to those produced in the older districts—this fact is probably due to the washing of berries in the clear running streams instead of in ponds which was the more common method in Upper Sarawak.

Pepper is also produced in Lundu and Simatan, but at the former place the gardens are dying out owing to the ravages of black berry disease.

It is said that the newly planted area in the 2nd Division has already been attacked by this disease.

Unless something is done to stop the spread of Voo, 'choon it would appear that the pepper industry of Sarawak is doomed.

BAZAAR GOODS FOR THE RED SEA DISTRICT.

The greater part of the 15,000,000 people, who occupy the 850,000 square miles of territory which make up the Red Sea district, live a very primitive existence. Their demands are not elaborate and are supplied almost entirely by petty traders and itinerant merchants. There are certain elementary articles which are required and which these merchants supply. At present these articles are bought in small lots separately, packed into boxes or bales suited for transport on camels, and thus hawked around the country. In the larger towns the same goods are retailed from small stalls. Aden merchants, writes the United States Consul at Aden, have conceived the idea of purchasing from Europe, America, or elsewhere, boxes already made up of assorted articles of the types finding a sale among the inhabitants.

Among the articles which find a sale at Aden may be mentioned laundry soap, sewing needles, thread, twine, writing paper, pencils, penholders

pens, ink in powder form, ink pots, small slates for use in the schools, blank books, pocket notebooks, penknives, scissors, purses, mirrors, handkerchiefs, socks and toys.

Before the war Germany and Austria supplied the bulk of these articles, and since the war the Japanese have largely secured the market. In all these cases, however, the sales have always been to concerns which resold the articles in small lots to the traders. Boxes already made up would, in the Consul's opinion, appeal strongly to the traders.

The dealers are all men of limited capital, and as a rule 45 to 60 days' credit is desired. In some cases, however, 25 per cent. would be paid in advance. Quotations in sterling are preferred by local merchants. For transportation on camel back the boxes should not weigh over 250 pounds each, which would permit two to be loaded on the animal.

The primary consideration on the local market in any case is cheapness. The Japanese goods are, for the time being, dominant by virtue of this advantage, but their inferiority of quality is very much disliked. Connections established in Aden would open a steady market and would penetrate the entire district.

COCA PRODUCTION IN JAVA.

The cultivation of coca was introduced in Java in 1880. There are now, principally in East Java, 63 estates comprising 6,000 acres planted in coca, according to official statistics. On practically all of these estates, writes the United States Consul at Soerabaya, coca is planted with coffee, rubber, and cacao, as a subsidiary crop. The plants are grown from seed and transplanted when they are six inches high; the first leaves may be gathered after a growth of eight months. Mature shrubs will yield from 700 to 850 pounds of leaves per acre. The bulk of Java coca is shipped to the Amsterdam market, the United States and Japan being the other principal purchasers. The exports of Java coca for the years 1916 to 1920, with the quantity shipped to the United States and Japan, were as follows:—

Year.	Total Exports.	Exports to United States.	Exports to Japan.
	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>
1916	897,600	600,600	4,400
1917	598,000	517,000	37,400
1918	1,456,400	897,600	558,800
1919	2,186,000	275,000	235,400
1920	3,755,400	24,000	649,000

Java coca has about the same alkaloid content as the Peruvian product. The basic alkaloid or Peruvian coca, however, is cocaine, while that of Java coca is cinnamylcocaine.

Journal of the Royal Society of Arts.

No. 3.637.

VOL. LXX.

FRIDAY, AUGUST 4, 1922.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C. (2)

REPORT ON THE "OWEN JONES" AND "MULREADY" PRIZES COMPETITION.

With the kind assistance of the Director of the Victoria and Albert Museum, the Council again arranged for a competition of students of Schools of Art in accordance with the terms of the Owen Jones Trust. Notices were issued in October last stating that six prizes would be offered under the usual conditions, each prize consisting of the Society's Bronze Medal, and a copy of a book or books on Applied Art, of a value not exceeding £2, to be selected by the successful competitors. In addition to these a Special "Mulready" Prize of £20 was offered for the best design (irrespective of class) submitted. The subjects of the competition this year were:—

ARCHITECTURAL DECORATION: Including Stained Glass, Mosaic for Walls and Floors, Plasterwork in relief and incised, Inlaid Marble and Stones, Lettering for Memorials.

WOODWORK AND CABINET WORK: Including Carving in Wood, Ivory and Bone, Inlay, Chairs, Chests, Cabinets.

TEXTILES*: Including Tapestries, Carpets and Rugs, Moquettes, Floor-coverings (*e.g.*, Linoleums and Floor-cloths).

The date for the receipt of competing designs was fixed for June 17th, 1922, and arrangements were made for their inspection at the Victoria and Albert Museum.

The following judges were appointed by the Council to consider the designs submitted:—Mr. J. H. Dearle, Mr. A. F. Kendrick (Department of Textiles, Victoria and Albert Museum), Mr. Eric Maclagan

(Department of Architecture, Victoria and Albert Museum), Lieut.-Colonel E. F. Strange, C.B.E. (Department of Woodwork, Victoria and Albert Museum), and Sir Frank Warner, K.B.E. Sir Charles Allom, Mr. Robert Anning Bell, A.R.A., and Professor Selwyn Image were also appointed, but were unable to attend.

The competition was in former years conducted by the Board of Education in connexion with the National Competition, but since 1917 it has been conducted by the Royal Society of Arts. The figures for the six years are as follows:—

Year.	No. of designs.	No. of competitors.	No. of Schools presenting candidates.
1917	120	73	22
1918	37	31	9
1919	50	31	9
1920	94	63	17
1921	237	181	36
1922	134	118	29

The centres represented were [the figures in brackets show the number of competitors in each case]:—Belfast (1); Blackburn (2); Bury (2); Bury St. Edmunds (2); Cheltenham (1); Coalbrookdale (2); Darlington (3); Dewsbury (13); Glossop (1); Guildford (1); High Wycombe (3); Leeds (8); Leyton (4); Liverpool (12). London: Battersea (1); Brixton (1); Hammersmith (5); Hornsey (5); Putney (4); Macclesfield (13); Manchester (2); Morecambe (1); Norwich (1); Nottingham (5); Portsmouth (2); Stockport (1); Sunderland (5); Watford (13); West Bromwich (4).

The designs submitted were divided as follows:—Architecture:—Decoration, 7; Memorial Tablets and Lettering, 18; Stained Glass, 12; Mosaics, 16.

Woodwork and Cabinet Work, 16.

Textiles:—Woven Fabrics, Tapestries and Carpets, 37.

* It should be noted that only the classes of Textiles mentioned above were eligible in 1922.

Floor Coverings, Linoleums and Floor Cloth, 22.

Printed Materials, Cretonnes and Wall Paper, 6.

The Judges regret that there was a considerable falling off in the number of designs submitted, as compared with 1921, although there is a marked increase, as compared with 1919, when the subjects of competition were the same as this year. Unfortunately the advance in the general standard of excellence, to which attention was drawn in last year's report, was not maintained. In the Tapestries, for instance, there was a great want of originality; the designs for linoleums were exceedingly commonplace, and the lettering, even though of better quality, was not free from faults. The Judges, therefore, recommend the award of only five of the six prizes offered, and the special "Mulready" Prize of £20. The awards are as follows:—

ARCHITECTURE.

Prize.

Rex W. Woods, School of Art, Norwich (Marble Memorial Tablet).

Commended.

James E. Connor, Ryland Memorial School of Art, West Bromwich (Design for a Memorial Tablet in Cast Green Bronze, $\frac{1}{4}$ scale, with full-size detail).

Lot Ramsden, School of Art, Leeds (Lettering in Marble).

MOSAIC.

Medal and Special Mulready Prize of £20.

Miss C. Honor A. Howard-Mercer, L.C.C. School of Arts and Crafts, Hammer-smith (Design for Mosaic with full size detail).

Commended.

Catherine M. Pargeter, School of Art, Watford (Design for Mosaic Floor).

WOODWORK AND CABINET WORK.

Prize.

Henry W. Keil, School of Art, Guildford (Looking Glass and Stand—Design and Work).

Commended.

Arthur Clegg, School of Art, Cavendish Street, Manchester (Carved Cabinet).

TEXTILES.

Prize.

F. Smith, Municipal Technical College, Blackburn (Woven Tapestry Work)

Commended.

John Burgess, School of Art, Macclesfield (Design and Draft for Woven Tapestry Panel; Woven Panel from above Design).

Fred Wright, School of Art, Macclesfield (Design for a Woven Tapestry Hanging).

Hilda Morfett, School of Art, Sunderland (Design for Tapestry).

CARPETS.

Prize.

Walter J. Bartrum, L.C.C. School of Art, Oxford Road, Putney, S.W. (Design for Wilton Carpet and Border for same).

Commended.

George Kershaw, School of Art, Macclesfield (Design for a Hand-Woven Carpet, Detail of Border, full size).

LINOLEUM.

Commended.

Ivan Stanway, School of Art, Macclesfield (Design for a Printed Linoleum).

Arrangements have been made for the exhibition to the public of the competing designs as in previous years. They will be on view from July 29th until September 17th, from 10 a.m. to 5 p.m. (on Sundays from 2.30 to 6 p.m.) in Room 132, Department of Textiles, Victoria and Albert Museum, South Kensington, S.W.

In announcing the awards, the Council desire to express their thanks to the Judges for the trouble they have devoted to the work, and for the promptitude with which the awards have been made.

They wish also to state their appreciation of the assistance rendered to the Society by the Director of the Victoria and Albert Museum and his staff.

The full conditions and arrangements for the Competition in 1923 will be announced later.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

INKS.

By C. AINSWORTH MITCHELL, M.A., F.I.C.

LECTURE I.—*Delivered January 23rd, 1922.*

It is 65 years since a communication was made to this Society on the subject of Inks, and as much knowledge has been gained since then, I venture to think that some record of the various investigations that have been made may be of general as well as specific interest.

In the paper read by Mr. Underwood in 1857 (*J. Soc. Arts*, 1857, p. 67), a brief outline was given of the history and processes of manufacture of writing, printing and copying inks, and certain criticisms were made and conclusions were drawn, to some of which I shall refer in the appropriate places.

Referring to the earliest type of writing inks, Mr. Underwood pointed out that their basis was carbon derived from lamp-black or some fine form of charcoal. There appears to be no doubt on this point, for we have no evidence as to the use of any other type of ink from the two oldest sources—China and ancient Egypt.

Fortunately in the case of China, a wonderful old manuscript by Chien-ki-Souen, dating back to about B.C. 2697, was unearthed. This was translated into French and published with its original illustrations by M. Jametel in 1892. The entire process of making Chinese ink, from the preparation of lamp-black to the moulding of the mixture of glue and black, is shown in these illustrations, some few of which are shown upon the screen. I think it will be generally admitted that, apart from their technical interest, these remarkable drawings, like much of the Chinese work, are most beautiful in design, full of vitality, excellent in composition and skilfully drawn.

The method of preparing lamp-black shown in the first diagram is essentially the same as has been used for thousands of years; that is to say, oil or other vegetable material is burned with a limited supply of air and the smoke collected in cold receivers, in this case made of terra-cotta. Much skill is required to stop the process at the right moment, to prevent the lamp-black becoming yellow. In order to have the lamp-black in a fine state of division

it is sifted into china vessels and dried and subsequently mixed and heated with a strained solution of glue and then pounded for hours. The resulting mass is made into sticks, which are afterwards moulded into cakes and dried in the ash from rice straw.

A rational development in the process is that mentioned by Julian (*Ann. de Chim.*, 1833, 53, 308), who, quoting from early Chinese documents, describes how the black was fractionated into finer and coarser qualities by conducting the smoke through a series of connected chambers made of bamboo covered with paper, the finest grade being deposited in the chamber furthest from the lamp. The principle of this method has also been used in modern methods of making lamp-black.

The rate of subsidence of the carbon affords a rapid means of testing the quality of Chinese or Indian ink. In applying the test, equal weights of the preparation are ground up with equal volumes of hot water, and the amounts of residue measured after similar periods of time. In this way it can be readily demonstrated that the best grades of Indian ink are composed of finer lamp-black than the commoner grades.

In general, Chinese ink, in sticks, contains about 8 to 9 per cent. of water, 52 to 54 per cent. of carbonaceous residue and 5 to 7 per cent. of nitrogen (derived from the glue), and yields about 3.5 per cent. of ash. Typical analyses will be found in my book on Inks (p. 29).

If we turn to ancient Egypt, we have not, so far as I am aware, any description of the methods of preparing inks, similar to the Chinese MSS., but we have actual specimens of the slabs and mullers used for grinding the ink, specimens of the early ink itself and innumerable examples of the ink in papyri and parchment documents. It seems probable that carbon ink was prepared in solid sticks as in China, although judging by the fact that fine reed pens were used on some of the papyri about the 7th century B.C. the ink must also have been used in a more fluid form. This is confirmed by the discovery of inkstands still containing some of the dried ink. Mr. A. Lucas, Director of the Government Laboratory in Cairo, has a paper in the current volume of "*The Analyst*" p. 9, on the subject, in which he gives an account of his examination of the remains of ink from an inkstand of the 16th Century B.C., and proves that the

basis of this is carbon. In fact, all the ancient Egyptian inks appear to have been carbonaceous in character, for such ink is present on potsherds, and on papyrus as late as the 5th Century B.C. I am indebted to Mr. Lucas for his kindness in giving me the opportunity of examining, not only such early specimens as these, but also in taking the trouble to send me various old Egyptian books and manuscripts and allowing me to show them here this evening. I have repeated much of his work on these actual specimens and am therefore in a position to confirm his results.

In Mr. Underwood's paper before this Society, the opinion was put forward that the inks in certain early writings alleged to have been carbon were probably mixtures of a carbon ink and an iron ink, since some were brown and others yellow in tint, and in his opinion this was hardly possible in the case of a pure carbon ink, since carbon was supposed to be quite unalterable. This question is among those dealt with by Mr. Lucas, who shows, first of all, that the writing on some old papyri is brown in colour and yet consists of carbon without any iron. This also applies to the ink on many later MSS., and it is significant that the change from what was, presumably, black to brown has in some cases only affected certain characters on a page. The probable explanation of this change from black to brown is that it is due to the impurities in the carbon, which in the case of inferior qualities was obtained from such materials as carbonised date-stones. Traces of tarry oils, and iron compounds would thus be introduced into the ink, and it is more reasonable to infer that the slight reaction for iron given by some old carbon inks is due to this cause, rather than to a deliberate mixing of two kinds of ink as suggested by Mr. Underwood. For example, in the old Arabic account book of 1181 A.H. (A.D. 1767) the ink gives a faint reaction for iron, but not sufficient to indicate the presence of an iron ink. The brown colour of some of the ink is also to be attributed to a fine coating of a glittering substance, possibly mica, used for drying the ink.

Carbon inks are still in use at the present day in Egypt. Mr. Lucas gives analyses of typical commercial samples, and it is interesting to note that in the case of the best quality of ink the rate of subsidence of the carbon is very slow. For example, best black writing ink, Tabrizy, contained

originally 16.1 grams of total solids per 100 c.c., whilst, after 8 years, the liquid above the deposit still contained 15.2 grams per 100 c.c. In the case of a poorer quality, however, the total solids had fallen in the same period from 12.0 to 6.2 grams per 100 c.c., and these contained no carbon, the whole of it having fallen to the bottom of the bottle. Both of these inks gave slight reactions for iron, obviously due to impurities in the ingredients.

The earliest known instance of the occurrence of an iron ink is in a parchment examined by Mr. Lucas dating back to the 7th or 8th Century A.D., which is a century or so earlier than has previously been recorded.

An interesting instance of the use of both a carbon ink and an iron ink in the same MSS. is to be seen in a portion of the Old Testament written in Arabic and bearing the Coptic date 1028 (A.D. 1312). The ink in most parts of the book is brown and has an iron basis, whilst in some pages the ink is black and is carbonaceous. The carbon ink gives slight reactions for iron, but there is no justification for concluding that carbon and iron inks have been purposely mixed.

From Egypt the use of inks spread into Europe, and the old Greek and Roman papyri frequently show very black writing, which is invariably due to carbon ink. An interesting historical example of Roman papyri was afforded by the fragments which were found in the ruins of Herculaneum and were examined by Sir Humphry Davy. No trace of any iron ink was found, and it would appear that the use of iron-gall ink was unknown to the Romans of that date, since it is not mentioned by Pliny. Carbon ink does not adhere readily to the surface of parchment, and it is not improbable that the adoption of that material as the medium to receive the writing had much to do with the replacement of carbon inks by iron-gall inks. The earliest reference to be found to the use of the latter is in a Cyclopædia of Christian Art written by a monk named Theophilus in the 11th Century, but the evidence that Mr. Lucas has been able to bring forward shows that iron inks were known three or four centuries before that date. In the 12th and 13th Centuries there are several references to iron inks, but it seems probable that the use of carbon ink was continued for a long period after the general adoption of iron inks.

Another ink, the basis of which is not carbon, but a carbonaceous pigment, is sepia, which is obtained from the ink sac of the common cuttle fish, *Sepia officinalis*. This has long been known as a natural ink, for allusions to its use are made by Cicero, and, later, by Persius (A.D. 34-62).

In preparing sepia, the ink sacs are dried and powdered, and boiled for some time with strong alkali. This extracts the pigment and, on then neutralising the extract with acid, the sepia is precipitated as a fine powder and is washed, dried and ground up and made into cakes or oil paints.

The pigment itself is a highly complex compound of a protein character. A specimen which I prepared and examined contained 8.4 per cent. of nitrogen and yielded 12.22 per cent. of ash. Different compounds to which names such as "melanin" and "sepiaic acid" have been given, have been isolated, but it is questionable whether these can be regarded as definite individuals.

Sepia is sometimes adulterated with brownish carbon, but the latter may be distinguished by the fact that it cannot be bleached by hypochlorites, and that it does not contain any appreciable amount of nitrogen.

The permanency of various pigments was investigated by Dr. Russell and Sir William Abney, and their results were communicated to this Society (*Journ. Soc. Arts*, 1889, 37, 113). Referring to sepia they pointed out that it was a popular mistake to regard that pigment as permanent since it was decidedly fugitive, as was shown by the fading of sepia drawings of the early 19th Century.

Iron gall inks are known to have been used in this country as early as the 9th Century A.D., for it was proved by Sir Charles Blagden (*Trans. Roy. Soc.*, 1787, 77, 451) that the writing on various vellum MSS. of that date and later, contained iron but no carbon. To quote his words: "No trace of a black pigment of any sort was discovered."

There are numerous early references to the methods of making iron-tannin inks. In the treatise of Theophilus of the 11th Century, to which allusion has been made, an extract of thorn wood is mentioned as the source of the tannin. This was evaporated to dryness and the resulting powder mixed with green vitriol (ferrous sulphate).

Another early reference is to be found in a treatise on metals (*De Rebus Metallicis*) which was written in the 11th Century by Albertus Magnus, and from that time onwards the preparation of iron gall inks is described by most of the early writers on natural objects.

An entire book on the subject of inks was written in Latin by Canneparius, Professor of Medicine at Venice, and an edition of this was published in 1660 in London. Referring to iron gall inks he quotes an Italian rhyme to the effect that the best ink was made by mixing one part of gum, two parts of green vitriol and three parts of galls in thirty parts of water.

At one time the preparation of ink was as much a part of the duty of the house-wife as the brewing of beer and making of bread, and the recipes for its manufacture were handed down within each family.

A number of such old household books are still extant, and that belonging to the Fairfax family was published in *facsimile* some years ago. Among the many recipes are several for making ink, the earliest of which, judging by the handwriting, is of the Elizabethan period. The preparation of ingredients in the different formulæ show wide variations. In two of them one ounce of copperas (ferrous sulphate) is used to two ounces of galls, whilst in a third the quantities are 4 of galls to 3 of copperas.

A curious book on writing, written by John de Beau Chesne and M. John Baidon, and printed at Blackfriars in 1571, contains directions in rhyme for making ink, in which the proportions given are 5 of galls to 3 of copperas.

It will thus be seen that these different formulæ must have produced inks of varying types.

In the 18th and the early part of the 19th Centuries the proportion of the two main ingredients was studied scientifically and similar discordant conclusions were drawn. For example, Lewis (1760) recommended the use of 3 parts of galls to one of copperas; Eisler (1770), 4 parts of galls to 2 of copperas; Ribeaucourt (1792), 2 parts to 1; Reid (1827), 1 of galls to 3 1/7 part of ferrous sulphate.

I have shown elsewhere ("Inks," Chas. Griffin and Co.) that these variations must be attributed to the fact that different kinds of galls contain different proportions of tannin, which is the active agent that

combines with the copperas. Hence it is essential that a formulæ should be based on the analysis of the particular galls in question. For example, it is quite practicable to make ink from the common galls found on English oaks, but these contain relatively so little tannin that three times as much would have to be used as of good Chinese galls, and more than twice the quantity required in the case of Aleppo galls.

Whatever the method of preparation used for these early inks the product was of a different type from the writing inks of the present day. The process then involved exposure of the ink for a considerable time to the air, so that the darkening process, due to the formation of a colloidal iron tannate, took place within the ink itself. The object of this practice was that the ink might not be too pale when first applied to the paper, but it had the drawback that the oxidation not infrequently proceeded too far and deposits were formed in the ink-pot.

In the modern type of ink the solution of iron tannate is kept, as far as possible, in an unoxidised condition and when applied to the paper at first produces only a faint buff coloration, which slowly darkens as it becomes oxidised, reaching its maximum intensity of colour in a period of days, weeks or months, according to the conditions. In order to give colour to the writing pending the formation of the true ink pigment, small proportions of indigo or aniline colours are added and the product is usually termed "blue-black ink," "violet-black ink," or the like.

The first reference to the use of indigo for colouring ink is that made by Eisler in 1770, and its use was introduced into this country by the firm of Stephens in 1836. It was first patented in Germany in 1856, by the firm of Leonhardi of Dresden, who claimed the use of both indigo and madder for the purpose and described his products as "alizarine inks." Subsequently, the madder was omitted, but the term "alizarine" was still retained.

If the inks prepared from ordinary gall extracts and tannic acid are to remain stable in the bottle, it is necessary to add a certain proportion of a free acid, which is usually sulphuric, hydrochloric or oxalic acid. This also has the advantage of causing the ink to penetrate the paper more readily, but, on the other hand, has the drawback of corroding steel pens.

In the attempt to produce an ink which would not have any corrosive action upon steel pens, various methods have been tried, but the most successful have been those based on the use of gallic acid. This acid is formed by exposing gallo-tannic acid derived from galls to a fermentation process, which is brought about by the action of certain mould fungi. It differs from gallo-tannic acid in being much less soluble in water (1 part in 130 parts at 12.5° C.) and in not combining with gelatin to form an insoluble compound. The compounds which it forms with iron, however, are much more stable in solution than the tannates of iron, and whereas the latter require the presence of acid to keep the ink stable, neutral solutions of iron gallate will remain unchanged for a long time and throw down but little deposit even when exposed to the air.

As against these advantages of stability and neutrality, gallic acid inks are generally regarded by ink-makers as being deficient in power of penetrating the paper, and they undoubtedly contain too little iron for a standard ink.

In some published formulæ, gallic acid inks are made by oxidising an extract of galls prior to the addition of the ferrous sulphate: this was first suggested by Reid in 1827. Such inks will usually consist essentially of a mixture of iron tannate and gallate, and will have some of the advantages of each.

With the exception of the introduction of gallic acid inks and of unoxidised inks of the "blue-black" type, the process of ink-making to-day is essentially the same as it was five hundred years ago.

Galls are crushed and extracted with water, and the extract treated with a solution of copperas (ferrous sulphate) in the proportion which has been found to give the best results in practice, with the particular galls employed. It is essential to economical working that a colorimetric estimation of all the tannin compounds in the galls should be made, since the preparation of gallotannic acid in Chinese or Japanese galls is much higher than in Aleppo galls, and different quantities of the iron salt will therefore be required.

After admixture of the main ingredients, the crude ink is allowed to stand in order to mature, and in this process throws down a heavy sludge, the amount and character of which will vary with the nature of the galls. The subsequent stability of the ink will

depend largely upon sufficient time having been allowed for this maturing process to be complete. The quantities of gum and provisional colouring matter to be used are, within certain limits, a matter of choice, but the amount of acid used to ensure stability must be kept at the point that is just sufficient for the purpose. If too much acid is used the ink will certainly be excessively corrosive, and may, under certain conditions, be decomposed.

In the preparation of gallic acid inks, which should be free from strong acid, it is necessary to choose a sample of copperas with as little free acid present as possible. In a discussion on a paper which I read before the Society of Public Analysts on this subject (*Analyst*, 1921, 46), Mr. Rudd Thompson suggested that ferrous ammonium sulphate might with advantage be substituted for ordinary ferrous sulphate in gallic acid inks, since it could readily be prepared without any free acid, and preliminary experiments which have been made have shown that the suggestion is worthy of the attention of ink manufacturers.

An interesting series of iron gallates has been prepared by Silbermann and Ozovitz (*Zeitsch. angew. Chem.* 1907, 2065), starting from a mixture of gallic acid and ferric chloride. This yields a chloro-ferric-gallic acid, which on treatment with ammonia is converted into a salt, ammonium oxy-ferric-gallate. When dissolved in water, this yields a solution which can be used as an ink. It gives violet-black characters which darken rapidly and after exposure to the air for about an hour cannot be removed by treatment with water.

Finally, I may refer to a new double iron salt which has recently been discovered and patented by Dr. Röhm. This is a ferric sulphate-chloride with the formula $\text{Fe SO}_4 \text{ Cl. } 6\text{H}_2\text{O}$. It is remarkably stable and is not hygroscopic or deliquescent. The great advantages claimed for its use in the making of ink are that it does not, like ordinary ferric salts, act upon aniline dyes, changing their colour, and that, unlike ferrous salts, it does not throw down a deposit when oxalic acid is used as the acid to render the ink stable.

LECTURE II.—Delivered January 30th, 1922.

The writing inks so far described may all be classified under the general term of "iron-gall inks," since, although different

raw materials are used in their manufacture, the active ingredient in each case is a tannic acid or one of its derivatives.

Of the numerous substances forming coloured compounds with iron salts, the tannic acids have been found by long experience to be the most generally suitable from all points of view for the purpose. There are, however, numerous other organic compounds which combine with metallic salts to form coloured derivatives which have a sufficient degree of permanency on paper to be termed inks; and, again, there are other metallic salts, besides those of iron, which will combine with tannin to form inks.

The property apparently depends upon the chemical constitution of the organic substance. Thus it was shown by Schiff (*Ann. Chem. Pharm.*, 1871, 159, 164) that when a substance gives a coloration with ferric salts, the presence of a hydroxyl group is indicated, whilst Schluttig and Neumann established the rule that in order to obtain an ink, as distinct from a fugitive coloration, the substance must contain three adjacent hydroxyl groups.

I have shown (*Analyst*, 1903, 28, 146) that this rule of colour grouping also extends to inks containing ammonium vanadate and similar compounds. I have also found (*Analyst*, 1920, 41, 126) that osmium tetroxide (the osmic acid of the microscopists) follows the same rule, and the ordinary one per cent. solution combines with gallotannic and gallic acids to form an ink, whilst with pyrogallic acid it yields a splendid black which attains its maximum intensity almost immediately after application to the paper. If it were not that osmium compounds are too expensive for the purpose an osmium pyrogallate ink would be a valuable addition to the inks now in general use.

The inks which, after iron gall inks, are the best known, are those made from logwood, which was first introduced into this country as a dye about the time of Queen Elizabeth.

The use of a decoction of logwood to improve the colour of iron-gall inks was known in the 17th Century and was studied by Lewis in 1763. In early inks it would, therefore, play the part of indigo in affording provisional colour.

The inks which logwood gives with iron salts form a green coloured stain which gradually darkens on exposure. By using

alum as the metal salt a violet-black ink is obtained, whilst potassium chromate gives a black ink which is extensively used in Germany as a cheap school ink, and to a less extent in this country.

The drawback of neutral chrome logwood inks is that they are liable to gelatinise in the bottle, and it is, therefore, necessary as in the case of iron tannic inks to have a certain proportion of acid in the preparation to give stability. An ink upon these lines prepared from logwood ink and bichromates has recently been described by Walther (*Chem. Zeit.*, 1921), in which the violet tint of the ink can be modified either in the direction of red or blue by regulating the amount of acid.

Ammonium vanadate behaves in a similar way to iron salts with gallotannic acid, and has, therefore, been used, either by itself, or as an addition to iron-gall inks, in various preparations. Unfortunately, although the ink gives a good black stain on paper, the writing is by no means permanent, and gradually turns yellow, even when protected from the light. So far, I have not discovered any method of preventing this, and it would, therefore, seem that the advantage of using such an expensive substance is questionable.

The discovery of aniline dyes added a new source of ink to those previously available. The first patent taken out in England for the use of these dyes as inks was by Croc in 1861, and in 1867 a solution of nigrosine was put upon the market under the name of "stylographic ink," since its fluidity renders it suitable for fountain pens.

Coloured aniline dyes have also to a large extent replaced the old natural dyes, such as cochineal and Brazil wood for red, indigo for blue, and Persian berries for yellow.

At the present day, the dye known as eosin, which was discovered in 1874, is widely used for red ink and "soluble blue" for blue ink, whilst there are numerous green, violet and yellow dyes available.

The great drawback of all ordinary aniline writing inks is their instability, and it has been shown by Cross and Bevan (*J. Soc. Arts*, 1891, 39, 152) that eosin and methylene blue are particularly fugitive.

In examining writing inks it is necessary in the first place to take into consideration the purpose for which the ink is primarily intended. For instance, the requirements for an ink for record purposes will differ materially from those for a fountain pen

ink. In the case of the former, permanence of the writing is the main consideration, and this can only be assured by introducing so much iron tannate or gallate into the preparation as to render it too thick for constant use in a fountain pen.

Many years ago the German Government laid down specifications for the composition of a standard ink, and their example has, within the last year or two, been followed by the British Government. In the specifications now issued to ink makers, it is laid down *inter alia* that an iron-gall ink for record purposes must contain not less than 0.5 per cent. of iron, and inks for fountain pens not less than 0.2 per cent. The lower limit must be regarded as the minimum in an ink the writing done with which may be accepted as reasonably stable. Hence, an estimation of the amount of iron in the ink is essential, and the maker's formulæ must be correspondingly modified in accordance with the analysis.

The degree of fluidity may be ascertained by estimating the amount of total solids in the ink. From 3 to 3.5 per cent. is a suitable proportion for fountain pen inks, whereas in the case of record inks, the proportion is frequently as high as 8 or 9 per cent. A simple and rapid method of controlling the degree of fluidity is to determine the efflux viscosity under standard conditions. The specific gravity is also a useful factor. For example, fountain pen inks usually have a specific gravity of about 1.015 to 1.020, whereas a record ink may give a result of upwards of 1.050.

The second essential for a good ink is that it should darken rapidly when exposed to the air on paper. This is conveniently tested by the method of Schluttig and Neumann, in which stripes of the ink are made upon standard paper fixed in a frame at an angle of 45°, the same quantity of ink being allowed to run from a pipette down the paper. The breadth and form of the stripes produced afford a preliminary indication of the character of the ink. When the ink is dry, the paper is left for eight days exposed to light and air and then compared with standard stripes made from a standard ink of specified composition. The paper is also cut into horizontal strips and different pieces immersed for some days in water, in 85 per cent. alcohol and in 50 per cent. alcohol, and the effects compared with those given by the stripes of standard ink.

The next essential of a good ink is that it shall be stable in the bottle and to a less extent in the ink-pot, and shall not change colour or form deposits prior to use. I have already mentioned that the final stability of the ink, in the case of gallotannic acid inks, depends upon the addition of the right proportion of strong acid and upon sufficient time having been given for the ink to mature in the factory. If too little acid has been added the ink will throw down a deposit; if too much, the writing will darken too slowly on paper and the pigments in the ink may even be bleached in the bottle, whilst steel pens are attacked to too great an extent.

The total acidity due to strong and weak acids in the ink may be rapidly determined after bleaching the ink with a measured quantity of hydrogen peroxide, whilst strong acids may be estimated by distilling the ink with sodium acetate and titrating the liberated acetic acid in the distillate.

In this connexion it should be mentioned that the bottles themselves should be tested for free alkali. During the past two years ink makers have had considerable trouble and numerous complaints from this cause. The ink would change its colour to dirty brown in the bottle and eventually throw down deposits or even become semi-solid. I have investigated numerous cases of this kind and have found the trouble to be solely due to the free alkali in the glass which gradually neutralised the free acid in the ink, with the result that the product became unstable and changed in this way. Gallic acid inks free from added mineral acid are also liable to be affected in this way and will change their colour and decompose if left in contact with alkaline glass.

It is remarkable that this factor should have been overlooked by ink manufacturers until I called attention to it last year (*Analyst*, 1921, 46).

The examination of ink in writing has frequently been found to afford conclusive evidence in criminal investigation. Under favourable circumstances it is possible to differentiate between two different makes of ink, or even between inks made by the same manufacturer at different periods. The theory underlying the method is that the two pigments, *i.e.*, the black iron tannate and the provisional dye, behave differently with various reagents and that the colorations produced will also vary according to the relative proportions of the

pigments. The tannins derived from different sources will also contribute their share towards the reactions, as has been shown by Schluttig.

Since the war there has been a less pronounced difference in the behaviour of different inks since there has been much less variety in the blue dyes available for the manufacturer. In applying the tests Osborn's comparison microscope is invaluable, since it enables the inks on different documents to be brought into juxtaposition within one field, this effect being obtained by means of prisms reflecting the two images into one eye piece.

This microscope has also been adapted for recording the colour either of the original ink or of the colorations produced by the various reactions. A description of the most suitable tests will be found in a paper which I read before the Society of Public Analysts (*Analyst*, 1908, 33, 80). These reagents include bleaching agents, oxidising agents and reducing agents, and reagents giving colorations with iron salts. The first occasion on which these methods were applied in an English Court of Justice was at the trial of the poisoner Brinkley, when it was proved that there were three distinct inks upon a forged will.

The question of determining the age of an ink in writing is a much more difficult problem, and it is only when the conditions are very favourable that a decided opinion can be expressed upon the point. There is, of course, a decided difference in the appearance of very old and of modern ink, apart from the fact that the edges of the lines in modern writing frequently show indications of the two points of a pen nib. In very old ink the surface of the pigment is broken up and irregular in its intensity, whereas in modern ink the colour is brighter and there is a sort of crystalline appearance, due mainly to the pigment attached to separate fibres of the paper.

The presence of a bright blue dye is also a distinguishing feature in many modern inks, and can be readily detected by the use of acid reagents which bleach the iron tannate, leaving the blue dye. Aniline dyes were unquestionably used in inks more than forty years ago, but their presence in the inks in entries in old family Bibles put forward as proofs that claimants for old age pensions were 70 years of age has on several occasions been fatal to the claim.

Evidence of a similar character was given at the trial of *Rex v. Menzies* in 1916, on the charge of uttering forged documents, alleged to date from 1719 to 1792, in support of his claim to a baronetcy. Aniline dyes were present in the inks which were, therefore, obviously not 18th Century inks.

In some cases inks have been artificially aged by the addition of Indian ink, but this can be readily detected by the use of a bleaching agent, which will decolorise the iron ink and leave the particles of carbon unaffected.

Occasionally, the colour of the ink affords some information as to its age. When a modern blue-black ink is freshly applied to the paper the change of colour from bright blue to what is apparently black takes place very rapidly at first, but the final change may not be complete for upwards of a year. Hence, if a record is taken of the colour of the ink in a given piece of writing and again after a few days, and it is found that a material change has taken place, there can be no doubt that the writing is comparatively recent.

Naturally, in such estimations, it is necessary to take into consideration whether the ink has been blotted, since the effect of blotting is to remove variable quantities of the two pigments present, and the final colour will also depend upon the lapse of time, in seconds, between the time when the ink was placed on the paper and the application of the blotting paper. The danger of losing sight of this factor is illustrated by the case of *Rex v. Cohen*, in which a charge of fabricating entries in a ledger was based on the fact that several of them were paler in colour than the adjacent entries. This was fully accounted for by differences in the times of blotting, and, apart from that, the sequence of the strokes of the writing, as compared with adjacent entries, showed that in the case of one of the disputed entries, at all events, the charge was not supported by the facts.

When two strokes made with ink at approximately the same time cross each other it is, as a rule, not possible to determine which stroke is uppermost; but, if one of the strokes is allowed to dry and a second then drawn across it, it is frequently possible to observe with the microscope that the more recent stroke passes above the other.

In this particular case parts of the lines

in the entry following the disputed entry in the ledger could be seen to be uppermost, thus proving that this entry had been made in its proper sequence.

Sometimes it is possible to prove the relative age of an ink in writing by means of chemical tests, although only in the case of inks, such as iron-gall and logwood inks, which undergo chemical changes after being applied to the paper.

All the tests of this kind which have been published depend essentially upon the same factor, viz., the changes in the chemical composition of the black pigment, the iron tannate, from a soluble into an insoluble form.

I have pointed out already how this change, which occurs by oxidation on exposure to the air, is indicated to the eye by a gradual darkening in colour, the black pigment formed blending with the original blue of the dye in the case of blue-black inks. But even when the maximum intensity of colour has been produced, the final stage at which the chemical compound in the ink on the paper becomes stable has not been reached, and a period of four or five years is required, under normal conditions, for its development.

From the results of a series of experiments, the details of which are recorded elsewhere (*Analyst*, 1920, 45), I have been able to give the probable explanation of these changes.

The ink in the liquid stage consists mainly of a soluble tannate. On exposure in a film to the air this slowly changes, firstly into a colloidal form, in which it will pass through coarse filter paper, and then into a tannate, which is insoluble in water, but will dissolve readily in dilute acids, and finally into a tannate which resists for a long time the action of dilute acids.

These several tannates appear to correspond with individual tannates which have been isolated.

The tannate insoluble in water which first forms is probably a compound, first prepared by Wittstein (*Jahresber. Chem.*, 1848, 28, 221), containing 5.53 per cent. of iron; and this, when exposed to the air, slowly changes into a tannate nearly insoluble in dilute acids; this contains about 8.0 per cent. of iron, corresponding with the requirement of a tannate prepared by Pelouze in 1833. Compounds containing proportions of iron between these extremes are probably mixtures of these two tannates.

At early stages, after being put upon the paper, the ink in writing probably consists mainly of a mixture of a soluble tannate and the tannate insoluble in water. One or more copies can, therefore, be taken from writing for some time, and upon this fact have been based tests for forming an estimate of the age of ink, such as were first proposed by Sittl in 1891, and by Habermann and Ossterreicher in 1901.

Any conclusions based on this method, however, are liable to be affected by the composition of the ink used, and it is only when the differences are very pronounced that any reliance can be placed on the results of copying tests. It may, however, under exceptional circumstances, be useful as a confirmation.

The difference in the behaviour of the earlier and later insoluble tannates is of more value. When writing, say, not more than one or two years old, is tested with a drop of dilute acid, such as 5 per cent. oxalic acid, it will react immediately and run over the paper; whereas an ink in writing of ten or more years of age will remain relatively unaffected for a long time. It is curious, too, that after the formation of the more insoluble tannate the blue dye also becomes protected from the action of the acid, and the ink in the writing does not smudge.

Before any conclusion can be drawn from the results of the test, it is essential that the chemical behaviour of each of the constituents in an ink should be known, that the differences should be very pronounced and that the dates of the writing should not be too close. In the case of *Rex v. Pilcher*, tried in 1910, all these conditions were present. The inks on an alleged will, stated to have been written twelve years previously, reacted immediately with different reagents, and the blue dye spread over the paper. Similar tests applied to documents of the alleged testatrix five or six years old showed no signs of diffusion, and there could be no doubt that the writing was not as old as was alleged.

Tests of this kind are obviously not applicable in the case of documents written with an aniline ink. Since such inks do not undergo oxidation to form a pigment, on exposure to the air, copies can be taken from them at any time until they have faded, and no difference will be observed in the behaviour of new and old writing.

The examination of ink on charred frag-

ments of paper requires special precautions, as was pointed out by Sir Humphry Davy in his account of the *Herculaneum papyri*. Even when the paper has been burned to a black cindery leaf, writing done with an iron ink may still be rendered visible under favourable circumstances, since the iron oxide from the iron salt in the ink will remain on the paper. The most suitable method is that first suggested by Habermann, of coating the paper with a solution of aluminium acetate or other salts and then gently igniting it, so as to leave a white coherent ash, upon which the iron can then be rendered plainly visible by treatment with a reagent. The principle is the same as that used in the manufacture of gas mantles.

LECTURE III.—*Delivered February 6th, 1922.*

I have already explained the reason why any iron-gall or logwood ink is capable of yielding one or more copies for some time after it has dried upon the paper, viz., that there is present an iron tannate which is still soluble in water, and only changes gradually into an insoluble tannate.

In the preparation of ordinary commercial copying inks, advantage is taken of this property, and the solubility of the partly dry ink is intensified by greatly increasing the proportions of the normal ingredients, and, in addition, adding a small amount of a substance such as glycerin, sugar or dextrin syrup in sufficient quantity to make the writing only very slightly sticky immediately after writing, and to be free from stickiness after the copy has been taken.

An ink prepared in this way will obviously yield copies for a very much longer time after writing than an ordinary iron-gall ink. Owing to their containing a considerable proportion of substances other than tannin, myrobalans are sometimes used in preference to galls as the tannin material for copying inks.

The new iron salt, ferric sulphate chloride, described in my first lecture, also makes a good copying ink.

An analogous principle is used in the case of logwood copying inks. In one method the colouring matter of logwood extract is oxidised with potassium bichromate in the presence of alum, and a suitable proportion of acid added to give the desired colour.

In the paper read by Mr. Underwood before this Society in 1857, an ingenious method of copying was described, the principle of which was that of using a decoction of logwood as the ink, and moistening the writing with potassium bichromate before taking the copy. Under these conditions, the ink is only formed at the time of writing, and several copies can be made. This copying method was patented (Eng. Pat. 1112, 1857), and was adopted by Government offices and important firms, but, like all the other early copying processes, it has been to a large extent replaced by the methods of carbon paper and stencil duplication.

A modern development of the copying principle is to be found in the so-called copying-ink pencils, which are used widely, although they are now seldom employed for copying purposes.

These pencils consist essentially of a mixture of graphite, china clay and an aniline dye, which is usually methyl violet, whilst some also contain wax. The proportions of these different components vary widely in different kinds of pencils, and it is therefore possible to distinguish between the writing done with them. For instance, in the case of some of the pigments, ether will readily remove the dye, whilst other pigments contain sufficient iron to give a pronounced reaction.

By means of a series of tests applied systematically, it was possible in the case of *Rex v. Wood*, to prove that the pigment in the writing on some partly burned fragments of card was of the same kind as that in a copying-ink pencil found on the prisoner, and different from the pigments in some twenty other kinds of copying-ink pencils.

Inks which may have been used even prior to carbon inks are those made directly from the juices of plants, and used for marking linen, and at one time also as writing inks.

To this class belong the preparations obtained from various species of *Rhus*, such as *Rhus toxicodendron*, the poison ivy of North America, which is still used as a stain for leather, and the juice of different kinds of *Coriaria*, such as *Coriaria thymifolia*, the "ink plant" of South America, which changes from red to black in the course of a few hours.

But perhaps the best known of these natural inks is that obtained from the so-

called "marking nut," the fruit of the Indian tree *Semecarpus anacardium*.

These nuts contain a viscid brown juice surrounding the kernel, and this, when extracted with ammonia solution, gives a dark fluid which produces a very permanent stain on linen. Lewis appears to have been the first to test the permanency of the stains (1763), and I can confirm his conclusions, for I found that the writing was fast to acids and alkalis, although the marks could be removed by means of ether.

Until comparatively recently the marking inks in most general use were those with a silver basis, frequently silver tartrate, which was reduced to a black silver oxide by the action of a hot iron. Inks of this type are still on the market, but are much less popular than aniline black inks. Inks containing gold and platinum salts have formed the subject of patents, but are obviously too expensive to be widely used.

One of the earliest types of aniline marking ink was that described by Jacobsen in 1867, which consisted of two solutions which were kept separate until just before use. One of these was a solution of aniline hydrochloride thickened with gum, and the other a solution of copper chloride, sodium chlorate and ammonium chloride. On applying the mixture of the two liquids to the fabric, a greenish stain, gradually changing to black, was produced, this being due to the formation of aniline black within the fibres.

Inks of this type are still to be bought, although they are gradually being displaced by aniline inks in one solution.

The principle underlying these inks is that of suspending the formation of the aniline black until the liquid evaporates, and it is by no means an easy matter to balance the two main constituents in such a way that the ink does not gelatinise into a solid black mass within the bottle. In some of these inks there is an excess of aniline over the oxidising agent, whilst in others there is both free aniline and acetic acid, but the exact composition and methods of making these inks are guarded as valuable trade secrets.

Some commercial inks contain salts of paraphenylenediamine, which is added to increase the black tone of the marking.

In examining marking inks the results of practical tests are of more importance than the composition of the preparation, although an analysis will show the general

character of the ink, and act as a control of the manufacturing process.

The analysis of a well-known silver marking ink gave the following results :—Water, 76.93 ; ammonia, 4.87 ; total solids, 23.07 ; mineral matter, 12.30 ; silver, 9.98 ; tartaric acid, 6.83 ; platinum, 0.26 ; substances insoluble in nitric acid, 0.11, and gum, 3.94 per cent. Extract of archil was present as the provisional colouring matter.

It is obviously a first essential that the ink should not injure the fabric. In the case of certain aniline inks which I have examined, the effect of applying dry heat too rapidly is to burn a hole in the material. This may be prevented by steaming the fabric or washing it with soap and water before applying heat, but one cannot always rely upon such precautions being taken.

The second requirement is that the ink should produce a permanent stain of a rich black tone. The tests to be applied include boiling strips of linen marked with the ink with soap and water, with strong sodium carbonate solution and with a dilute bleaching agent, and noting in each case to what extent, if any, the marking has faded.

The early history of printing inks was discussed by Mr. Underwood in the paper read before this Society, and I can confirm his observation that the ink used in the early block books is inferior to that found in the early books using movable type ; apparently the latter contained a purer form of carbon.

The earliest block book in the British Museum dates back to 1470, and there is some reason to question the belief that block printing preceded the use of movable type, at all events in Europe. In all probability, printing ink, which was used either with blocks or movable type originated with the Chinese, who had only to add a drying varnish to their ordinary carbon writing ink to obtain a suitable medium for the purpose.

One of the earliest descriptions of the manufacture of printing ink is that given by Canneparius in his book *De Atramentis* to which I have already referred. This ink consisted of a mixture of lamp-black, linseed oil and juniper gum, which was heated over a slow fire until sufficiently thickened.

Moxon in his *Mechanick Exercises* (1683) states that Dutch printing ink of that date was superior to the English product, and

he attributes this difference to the use in this country of too much resin and to the admixture of train (*i.e.*) blubber oil with the linseed oil, which caused the ink to become oily and to separate in the printed page.

Savage, who wrote on *The Preparation of Printing Ink* (1823), considered that Moxon was justified in his criticisms of the English printing ink of the seventeenth century, but asserted that the English ink of the early nineteenth century was much superior to the ink made by the early Dutch method. He considered it essential to carry the heating of the linseed oil to the stage technically known as "burning."

A standard ink based upon similar lines to Moxon's Dutch ink, was made by Breton, printer to the King of France, in 1751. The varnish was made by boiling nut oil (*i.e.*, walnut oil) for two hours, and then removing the cover so as to "burn" the oil, this process being repeated several times. The use of litharge was condemned as being liable to cause the ink to clog the type.

Since the day of Savage various modifications in the process of preparing the lithographic varnish have been devised, and it has been shown that the method of "firing" the oil is not an essential part of the process.

It is important to use an old well-matured oil for the purpose, for crude oil contains impurities which will interfere with the colour and the yield of the varnish. In this respect modern experience confirms the statements of the older writers, such as Moxon and Savage.

In some of the modern processes of making the varnish steam-jacketed kettles are employed, whilst in others the oil is heated by means of a steam coil, while air is blown into it through a series of small orifices. Varnishes made by heating the oil with superheated steam dry rapidly, but are often much darker in colour than those consisting of oil "boiled" by the older processes.

In order to prevent such discoloration in the preparation of the varnish, processes in which the oil is oxidised at a moderate temperature by means of oxygen are sometimes used, whilst in other processes ozone is used as the oxidising agent.

The substances which are introduced into the varnish, either to obtain a cheaper product or for some special purpose, include various resins, oil of turpentine, semi-

drying oils, such as soya bean oil, paraffin oil, "driers" of various kinds and soap. In the case of the so-called "gloss ink," a rapid drying copal varnish is often added.

The nature of the substances to be added will depend upon the use for which the ink is intended. For rapid newspaper work, for example, a cheap ink which dries rapidly is required, whilst for the finest book work a pure pale oil varnish is essential, and the rate of drying is of secondary importance.

The blacks used in printing ink range from common pigment such as bone-black (made by calcining bones) or vine black, also known as vegetable black, which is obtained by carbonising vegetable material to pure carbon blacks, such as lamp-black and gas black. Modern lamp-black is prepared by processes analogous in principle to some of the early Chinese methods. It is made either from oil or from pitch, resin and the like. For example, in Dreyher's apparatus gas derived from vaporised resin is burned in a series of lamps beneath a rotating cylinder upon which the black is deposited, and subsequently removed by means of iron catchers coated with flannel. The best kind of lamp-blacks are obtained by a fractionating process analogous to that already described as being used by the Chinese.

The best kind of black is that commercially known as *gas black* or *carbon black*, which is now prepared in large quantities from the natural gas issuing from the oil wells in the United States. This is mainly made by the so-called "Channel" process, in which the gas is burned in a series of jets beneath steel channels grouped in tables of eight, and the black deposited on the smooth underside of these is scraped off into hoppers through a reciprocating motion of the channels.

Various factors, such as the pressure of the gas, the air supply and the speed of scraping, all have an influence on the quality of the product.

In examining gas blacks or lamp blacks, the "strength" or tinting power is determined by mixing weighed quantities with zinc oxide and oil, and comparing the tone with that given by a standard black under the same conditions, whilst the richness of tone (or colour) is compared in the same way with the standard black mixed in the same proportion with oil.

The carbon blacks upon the market vary considerably in composition. Analyses by

Perrott and Thiessen (*J. Ind. Eng. Chem.*, 1920, 12, 234) show the following extremes: Amorphous carbon, 85 to 90 per cent., water, 1 to 7 per cent.; hydrogen, 0.5 to 0.8 per cent., and oxygen 2 to 8 per cent. Some degree of relationship has been established between the composition and the behaviour of the blacks in printing inks.

The mineral pigments commonly used for printing inks include vermilion for red; Prussian and other ferrocyanide blues, and ultramarines; chrome yellows, chrome greens, chrome yellow orange (a mixture of normal and basic lead chromate), orange mineral (a combination of lead oxides), Indian and Venetian reds, burnt umber and burnt sienna for browns.

In examining these, the tests to be applied include the colour, the covering power, fineness of division, miscibility with oil, and absence of grittiness. Organic lakes, consisting of dyes fixed upon a base such as alumina, are important pigments, and alizarine pigments and diazo dyes are superior in permanency to light to many of the mineral pigments.

The property of "bleeding" or forming a solution in the oil medium of the ink, is associated with some of the aniline dye lakes, and these are quite unsuitable for the manufacture of printing inks.

One of the main essentials in the preparation of printing ink is that the pigment should be an absolutely uniform state of fine division and be free from gritty matter, and that it should be perfectly and evenly incorporated with the oily medium. The more recent developments of the manufacture are in connection with machinery, such as grinding and incorporating mills, designed to effect perfect admixture.

As in the case of marking inks, the results of physical tests and of trials under the conditions for which the preparation is intended, are of greater importance than a chemical analysis, although this is sometimes necessary.

In addition to the properties already mentioned, practical tests should be made of the drying power, the flowing capacity, permanence to light and air, absence of "bleeding," or of "striking through" the paper, and the behaviour on the printing press.

The invention of the typewriter involved the production of a new kind of ink with properties intermediate between those of

printing and writing inks. Most of the machines on the market supply the ink to the type either by means of a ribbon or a pad, previously saturated or coated with the ink.

Many of the inks are still composed of a saturated solution of an aniline dye, such as methylene blue or methyl violet, with the addition of a suitable proportion of glycerin or other medium to give the necessary thickness to the solution, and to prevent its drying up completely within the ribbon or pad. In some of the inks the dye is used in the form of a lake.

An excess of glycerin is objectionable, since it causes the ink to yield smudged impressions, and this ingredient is, therefore, omitted in the best modern inks. One pad which I recently examined was saturated with methyl violet and a marine animal oil, probably menhaden oil. This was not a good medium for the purpose, as it did not dry with sufficient speed. The media used in other inks include mixtures of vaseline, oleic acid, castor oil, wax, etc.

Some of the black inks consist of a solution of nigrosine, whilst induline dyes are used to produce a very dark blue writing which resembles superficially the colour of a blue black ink in its later stages.

Most of these aniline inks are open to the objection that they give fugitive writing, and in some cases typed documents have been known to fade completely in the course of a few years. There are, however, numerous typing inks to be obtained which are much more permanent, and these contain finely divided carbon such as lamp-black or carbon black with, sometimes, also an aniline dye such as nigrosine. Finely ground mineral pigments, such as Prussian blue and vermilion substitutes, are also used in admixture with a mineral oil.

In the case of inks for ordinary correspondence, it is necessary that it should be possible to rub the writing out without leaving a smudge, but for record purposes the writing should be capable of resisting both chemical agents and mechanical treatment. Experiments which I made for one of the leading manufacturers indicated that it would be a great improvement if colloidal carbon were used in place of ordinary lamp-black for this purpose. In the use of such colloidal preparations of carbon is also to be found the solution to the problem of preparing a safety ink, that is to say, an ink which cannot be removed from a document without detection.

Acheson's colloidal graphite, which is made artificially and converted into a form in which it will remain suspended indefinitely in a liquid medium, is perhaps the best known example of this kind of carbon. Lamp-black can also be prepared in this form.

Several of the so-called safety inks sold in this country and in the United States contain a suitable proportion of this carbon pigment suspended in a solution of an aniline dye or other soluble colouring matter, and some of them, if left for a sufficient time before blotting, will penetrate well into the paper. A want of penetration is the weak point of many of these inks, which will resist chemical agents satisfactorily, but can be removed by mechanical treatment, such as brushing the surface of the paper under water.

Prior to the War, the so-called sympathetic inks, or inks for secret writing, were of very small importance. They had long been known, and were usually regarded as scientific toys. Even in the days of Pliny it was known that the juices of certain plants would remain invisible until heat was applied to the paper, causing carbonisation of the acids or carbohydrates in the juice.

Robert Boyle (1663) refers to some of these inks, and the use of salts of cobalt for this purpose was described by Waiz in 1715.

The solution of any salt which is colourless or nearly so, when applied to paper, but forms a dark compound on treatment with a reagent, can be used in this way. For example, an extract of galls would be practically invisible on paper, but would give a black ink on treatment with an iron salt, and so on.

During the War, various methods of secret writing were used by German agents, and particulars of the substances used were from time to time made public property, by being published in the press. For example, it was commonly known that the earlier agents were using the very primitive method of writing in lemon juice, although in the case of Kuepferle formalin was also used, probably since it has the effect of causing the writing to require greater heat for development. In that case, traces of formalin could be detected on the pen, actual vegetable particles were adhering to it, and the washings from the nib gave the reactions of a fruit acid, whilst on the other hand a cut lemon, found in the

accused man's room, gave a reaction for iron at the place where something had been inserted into it.

Later, it was also published that some of the agents had been using ferrocyanide, a solution of which salt is practically invisible on paper, but gives a blue Prussian-blue colouration with an iron salt.

The Germans were undoubtedly well acquainted with the principal methods of secret writing, for the methods of producing such writing and of testing documents to discover its presence are fully described in works on forensic chemistry published long before the War. For example, in Dennstedt and Voigtlander's *Lehrbuch der gerichtlichen Chemie* (1906), the methods of testing described, include treating portions of the document with dilute ink and exposing it to the vapour of iodine.

It is pointed out that ink is an effective developer for writing done with ordinary saliva, and that iodine vapour is the most generally useful reagent for every description of secret writing.

Experiments which I have made to ascertain the action of ink in developing saliva writing have shown that it is partly physical and partly chemical. By adding saliva to ink, the formation of Pelouze's insoluble tannate (containing 8 per cent. of iron), is accelerated, and thus ink will darken more rapidly at the point where the saliva has dried upon the paper.

At the same time, if the surface of the paper has been scratched, there will be increased absorption of colouring matter where the sizing has been removed, so that in that case the development is also a physical process.

I have not, however, found any reference in German scientific literature to the use of solutions of colourless substances which become fluorescent under the influence of ultra-violet light. I called attention many years ago to the advantage of such a method, in the first edition of the book on *Inks*, which I wrote in collaboration with Mr. T. C. Hepworth.

NOTES ON BOOKS.

THE JOURNAL OF THE INSTITUTION OF ENGINEERS (INDIA). Vol. II. April, 1922. Calcutta: D/5, Clive Buildings.

This volume contains a record of Proceedings of the second General Annual Meeting of the Institution, which aims at fulfilling, for India, the functions fulfilled for England by the corres-

ponding Institution in England, or for America by the American Society of Civil Engineers.

From the report and statement of accounts for the year ending 31st August, 1921, it appears that the Institution of Engineers (India) has not yet arrived at a condition of assured stability, its members (or subscribers) amounting to only 421 so far, as compared with an estimated requirement of 780 members for purposes of financial stability. The Institution is, however, still in its infancy, and its organisers are confident of ultimate success, a confidence which we cordially hope will be justified by events.

Amongst the professional papers read at its second Annual General Meeting on the 30th January, 1922, the place of honour has been accorded to an interesting monograph by a non-engineer—a geologist, Mr. Cyril S. Fox—on "Some Engineering Aspects of Geology."

The greater portion of his paper is devoted to a discussion of rocks (as distinguished from agricultural soils), minerals, structural geology, stone-quarrying, stability of hill-slopes, stability of artificial tunnels and dams; and these subjects he discusses obviously as an expert, with a facility of lucid illustration which will probably be useful to, and much appreciated by, young civil engineers.

Here and there in his paper we find occasional slips; as, for instance, where he mentions Viceregal Lodge, at Simla (instead of the Town Hall, Simla), as an example of a building, the stone for the construction of which was not selected with sufficient care before it was utilised for that purpose.

Another good paper, in the same volume, is one on "The Water Supply of Bengal Towns," by Mr. J. Bransby Williams, M.I.E. (Ind.), Chief Engineer, Public Health Department, Bengal.

Mr. Williams explains that the peculiar difficulty of urban water supply projects in Bengal is that supplies are limited by financial considerations in a manner that is not experienced in countries with a higher standard of living and individual wealth.

In illustration of his meaning, he assumes statistics of a waterworks installation in an average *mofussil* (country town) in Bengal. The capital cost of the works is Rs 2000 (£133) per 1,000 gallons of water supplied daily throughout the year; and working expenses threepence per annum for the same unit of supply. It is customary for the Local Government to present the municipality with a free grant of one-third of the capital cost, so that the latter has to find capital to the extent of £89 only per thousand-gallon unit. Expenditure has to be incurred annually to the extent of 7½ per cent. of the capital cost, in interest charges and liquidation of capital; and this amounts to 4½ pence per unit per annum. Thus the total annual cost of water supply is 7½ pence per unit. The rateable value of the town is less than 16

shillings per head, and the maximum water rate that can be levied is $6\frac{1}{2}$ per cent. of rateable value, or, say, $1\frac{1}{2}$ shillings per head per unit of supply per annum; or $1\frac{1}{2}$ pence per mensem; or 0.057 pence per diem. And the maximum quantity of water that can be supplied (consistently with sound finance) for that sum of 1000×0.057

money would be $\frac{57}{7.34}$; or rather less

than 8 gallons per head per diem.

On the other hand, the members of Bengal municipal bodies point to the fact that the allowance of water in London is from 40 to 50 gallons per head per diem, and in some American cities over 200 gallons; and they argue that in a tropical climate like that of Bengal a supply of 15 gallons per head per diem ought not to be regarded as excessive. To reconcile financial considerations with arguments of this sort: "*Hic labor, hoc opus est.*"

Mr. Williams's remarks on the subject of subsoil water flow seem to be generally sound.

The only other paper we need notice here is one on "Hydro-Electric Power in Mysore," by Mr. S. G. Forbes.

Mr. Forbes is apparently an electrical engineer and a hydro-electric enthusiast. He starts by quoting from a report written by himself in the post-war enthusiasm of 1918:—

"The Great European War has taught . . . the tremendous importance of the industrial development of all the resources of the nation until all the needs for carrying on the peace-business of the nation, and if necessary for conducting an aggressive and successful war, can be met to the fullest extent possible from those resources within the nation Probably the most important single question arising out of these investigations is the conservation and economical use of our resources of coal, oil, and wood. These resources are not inexhaustible, and we are using our capital when we consume them, for whatever purpose, and we should . . . bend our energies towards . . . the substitution therefore of power derived from some other source." Hydro-electric power suggests itself as this other source; and Mr. Forbes gives a description of the Cauvery Power Scheme in Mysore "as an illustration of what may be done with a potential water power situated within a reasonable distance of an industrial centre, and also because it is one of the very few 25-cycle systems in India."

He compares the progress of hydro-electric power development in Mysore with that of the Province of Ontario, Canada, and with that of the whole of the United States of America; and he goes on to write:—

"Most of the water-power in Mysore, by reason of the present stage of industrial development and price of fuel, is not economically available. It simply represents a potential asset to be made

available as the price of fuel increases and industries are forced to take it up. The increasing cost of fuel, so long ago as 1900, forced the development of the Cauvery Falls, and the transmission of the power 92 miles to the Kolar Gold Fields, where it was used to displace steam power. . . . The steady decrease in the supply of fuel and its corresponding increase in cost has been so active in Mysore and Bangalore that power from fuel has been almost completely displaced by hydro-electric power, releasing the fuel for domestic purposes and such industries as inherently require fuel for heat. The electrification of the railways is under investigation, and when the conditions of traffic and fuel costs justify, the change from steam to electricity will be made."

All this is interesting and instructive. Mr. Forbes's account of the development of hydro-electric power in Mysore is a history of progress on sound commercial principles. So long as coal or wood fuel was available at economical rates of cost, the Mysoreans used it for all purposes; but when these kinds of fuel became scarce, and their prices prohibitive, the business enterprise of the local industries substituted cheaper power derived from hydro-electricity. This being so, one is not quite prepared to follow the further development by Mr. Forbes of his views, as follows:—"The development of hydro-electric power has been brought about by economic conditions which, until the War, were not fully understood, or to which we did not give sufficient heed. The sooner we get rid of the idea that such undertakings are investment schemes, and realise the conditions that are compelling us to economise, the better it will be for the fuel supply of the future generations."

Apparently in Mr. Forbes's opinion, the development of hydro-electric power in Mysore has been on the wrong lines and on economically false principles. His idea appears to be that even if there had been, down to the present day, plenty of cheap wood and coal fuel in Mysore, the people should have refrained from using it, and should have kept it in reserve as "capital," with a view to the possibility of the utilisation of it at some future date, by a future generation of Mysoreans in the prosecution of an "aggressive and successful war." In the meantime, they should have developed (and paid for) hydro-electric power at a greater cost and kept their wood and coal "capital" idle for the benefit of future generations. This seems to be rather an extreme illustration of hydro-electric enthusiasm; likely to be less convincing in the year 1922, than it might have been in 1918.

It is probable that neither in America nor elsewhere in the world has hydro-electric power been developed on a large scale, except in cases and places where it could be produced at a cost low enough to enable it to compete successfully

with power generated by wood, coal, oil or other source of energy Mr. Forbes's sketch of the hydro-electric installations in Mysore is interesting, but his reference to this enterprise seems to be mainly an argument of propaganda in favour of hydro-electric power development regardless of cost

Other papers in the Journal are entitled: "Organisation of Ordnance Factories," "Sub-soil Percolation," and "Flood Absorption in Tanks."

GENERAL NOTES.

INDUSTRIES OF THE ISLAND OF GOZO.—The Island of Gozo, the smaller of the two inhabited islands of the Maltese group, has an estimated population of 24,080, and an area of 20 square miles, most of which is devoted to agriculture. Clover, grain, and cotton were the principal crops raised during 1920-21. There was a large quantity of eggs exported for consumption in the island of Malta. In previous years a considerable quantity of wine was exported to Malta, but, according to a report by the United States Vice-Consul in Malta, the vineyards gave a poor yield last season. The other local industry is lace making, which, for the last five years and up to the present time, has been on the decline owing to the scarcity of demand in foreign markets

DEVELOPMENT OF BRAZILIAN OIL NUT RESOURCES.—A bill has been introduced into the Brazilian Congress providing for the protection and development of the oil-nut resources of the country. The numerous varieties of nuts growing in the northern sections of Brazil have high oil content and are in demand because of their food value and lubricating properties. According to a report by the United States Assistant Trade Commissioner at Rio de Janeiro, an important trade could be developed by the proper culture and handling of these nuts, and it is to this end that an experiment station is being proposed.

VALUE OF THE POULTRY INDUSTRY IN THE UNITED KINGDOM.—In 1920, according to the *Journal of the Ministry of Agriculture*, the United Kingdom imported eggs and poultry to the value of £18,759,856, exclusive of imports from Ireland. Irish exports were valued at £18,236,406 in 1919, the bulk of which came to Great Britain. Thus the value of eggs and poultry imported into Great Britain during 1920 probably reached the figure of £36,000,000. The value of eggs and poultry produced in the United Kingdom in 1920 is believed to have been between £50,000,000 and £60,000,000, whereas the estimated value of the wheat crop in the United Kingdom for 1920 was approximately £31,000,000.

VICTORIA AND ALBERT MUSEUM.—The Victoria and Albert Museum has acquired, by gift, the throne of the Emperor Ch'ien Lung. The Museum was given an option of purchase on exceptionally favourable terms, but its resources were unequal to so large an undertaking; fortunately a private donor, Mr. George Swift, has provided the whole of the sum required. The throne was one of a pair, formerly in the Palace of Nan-Haidze, near Peking, its companion being, it is believed, in the possession of the President of the Chinese Republic. It was made in the Imperial Lacquer factory maintained by Ch'ien Lung for that Emperor's personal use. With the exception of the seat, which is of fine flat red lacquer with floral decoration, it is executed throughout in carved lacquer of superb quality and workmanship, mainly red, but with layers also of green in two shades, brown and yellow. The decoration is symbolical throughout, of good fortune, longevity, married felicity and other matters of good omen: the centre panel of the back having for its chief feature the elephant bearing a vase of jewels—a rebus signifying "Peace reigns in the North." The throne is 3ft 11ins in height, 4ft 1½ins in width and 3ft in depth; and the seat is still furnished with its original cushion of fine old brocade.

INDIAN CINCHONA BARK AND MYROBALANS.—A new volume in the series of Reports of the Indian Trade Enquiry conducted at the Imperial Institute, published by Mr John Murray, deals with cinchona bark, the source of quinine, and myrobalans. At the present time Java has a virtual monopoly in the production of cinchona bark, its closest competitor being India, which produces only about 8 per cent of the world's supply. Moreover, the manufacture of quinine is largely under the control of Dutch interests, and of the 8,000,000 oz. used annually in the British Empire about 5,000,000 oz. have to be obtained from foreign sources. It is suggested that attempts should be made to produce in India sufficient bark to meet a much larger proportion of the Empire's requirements. Cinchona has been introduced into several tropical parts of the Empire, and the volume records the results of examination at the Imperial Institute of cinchona bark grown in St. Helena, Tanganyika, and the Cameroons. Myrobalans, the dried fruits of a large tree, form one of the principal tanning materials used in India and are also largely exported. The quantity reaching this country has varied in recent years from about 500,000 cwt. to over 800,000 cwt., whilst prior to the war Germany and the United States were also large importers. Particulars are given in the Report as to the trade in myrobalans, their composition, and their use by British tanners and dyers, whilst suggestions are made with respect to the future trade in this product.

PROCEEDINGS OF THE SOCIETY.

TWENTIETH ORDINARY MEETING

WEDNESDAY, 26TH APRIL, 1922.

SIR JOHN F. C. SNELL, M.Inst.C.E.,
Chairman of the Electricity Commissioners,
in the chair.

THE CHAIRMAN, in introducing the reader of the paper, said that after the great world cataclysm through which we had passed, anything which was done by our great Societies to make industry more efficient and intelligent was worthy of most grateful acknowledgment. The cataclysm had left us in the material sense a poorer nation, recalling to some extent the condition which obtained at the close of the Napoleonic wars, when, but for one thing, the nation would never have made the recovery which it did. That one thing was the invention of James Watt. It was the utilisation of steam which enabled the country to develop into the great industrial position which it had since reached. The position to-day, however, was not analogous because since the Napoleonic wars other nations which were active industrial competitors had arisen. The question was what could be done to-day to bring about a similar revival of industry to that which took place after the Napoleonic wars. He would not suggest that it was wholly electrical development which was going to do this, but certainly this was going to be an important factor. Anything, therefore, which encouraged manufactures and commerce must be of material assistance at this juncture to the nation at large. He welcomed such a paper as was proposed for that evening as contributing to that revival. Dr. Crowley was a colleague of his on the Electric Power Supply Committee during the war, and it did not take his colleagues on that Committee very long to size up his great capabilities, and it was with the greatest pleasure that later he (the speaker) was able to welcome Dr. Crowley as a member of the Water-Power Resources Committee. He was reminded of a character in *Westward Ho!* who said that the reward for being faithful over little things was to be found in having greater things to do, for Dr. Crowley was rewarded by being made Chairman of two sub-committees which really did most of the important work of the main body. Those

who had seen the report of the Water Resources Committee would realise the immense amount of work which must have fallen to his lot. It was with the greatest pleasure, therefore, that he introduced him to the meeting and called upon him to read his paper.

The paper read was:—

THE USE AND ADVANTAGES OF ELECTRIC POWER IN THE FACTORY, AS ILLUSTRATED BY ITS APPLICATION TO THE JUTE INDUSTRY.

By J. F. CROWLEY, D.Sc., B.A., M.I.E.E.

SYNOPSIS.

I. General

II. The alternatives open to manufacturers as regards power.

- (a) To purchase power from outside sources.
- (b) To generate power themselves. The choice open to the manufacturer decided mainly on the basis of cost; but there are the following points in favour of outside supply:—

- (1) It leaves more capital available for textile plant.
- (2) Enables the management to concentrate on manufacturing processes.
- (3) Permits of easy and gradual expansion to meet requirements (c.f. mobilisation for munitions in Great Britain).

III. Where the manufacturer generates power himself, the principal prime-movers he has to choose from are:—

- (1) The Steam engine
- (2) The Steam turbine.
- (3) The Diesel engine

Shows how a steam turbine best meets the driving criteria laid down.

IV. The principles governing power applications.

- (a) Building requirements must be little, if at all, in excess of those required by the manufacturing processes.
- (b) It must be possible to arrange lay-out of plant to best suit manufacturing processes, lighting, accessibility and supervision.
- (c) The equipment must be reasonable in first cost and in running costs.
- (d) It must be possible to secure the maximum production from the machines.

- (1) By ensuring reliable running. (2) By maintaining the average speed within the defined limits. (3) By keeping the "cyclic irregularity" within the defined limits.

V. How the driving principles laid down are affected by:—

- (1) External conditions such as climate. (2) The nature of the manufacturing processes. (3) The peculiarities of particular machines.

VI. The importance of an exact knowledge of the requirements of an industry and its manufacturing processes when applying electrical drive in accordance with the principles laid down.

VII. The jute industry and jute manufacturing processes with their respective power requirements.

VIII. Methods of distributing and applying the power in the factory.

IX. Shows how electricity best meets the driving criteria laid down, keeps shafts within reasonable dimensions and speed variation within any limits desired. Shows how electricity can be as bad as the worst mechanical drive or better than the best, depending on how it is applied.

X. The application of electricity—

- (a) Group driving in large units.
(b) Group driving in small units.
(c) Individual driving.

The best combination of all these depends on each individual case.

XI. Increased production the only salvation for factories put down during or since the war with high capital charges. The real advantage of electricity lies in the increased production resulting from its use, and indicates how a given increase in production affects profits.

XII. Special considerations applying to India.

XIII. Conclusion.

The statement was made a few years ago in the report of an important Government Committee* that "one question which has been settled conclusively during the past 15 years is that the most economical method of supplying power to industry is the electric motor, which, on account of its high efficiency, has ruled out all rivals so far as the workshop itself is concerned."

The author felt at the time this report was issued, and still feels, that this and similar statements were of too general and far-reaching a character and unlikely to be accepted without evidence by the bulk of moderately large power users. Both engineers who are engaged in developing the power loads of electricity supply stations on the one hand, and in promoting the sale

of electrical manufactured goods on the other, realise very fully that in general where the problem of driving is under consideration by manufacturers, a strong case has to be made in each instance on economic grounds for electricity, before the manufacturer can be induced to adopt it in preference to installing his own prime mover with mechanical methods of power transmission. Further, in the majority of cases where electricity is adopted in the factory, its adoption is not based on a saving in power due to motor efficiency or on a reduction in transmission losses, nor even on the grounds of cheaper power costs, but because of an increased output from the manufacturing plant which inherent qualities in electrical transmission enable the application of electricity to give.

During the last few years, owing to the action of the Government in appointing on the report of the Electricity Supply Committee of the Board of Trade, Commissioners with comprehensive powers to deal with electricity supply, there has been a very distinct development in the provision for Great Britain of a cheap supply of electricity from central sources. This development has definitely accentuated a tendency already apparent for power users to purchase power from public supply authorities, rather than generate themselves, in other words, towards the "collective method" as distinct from the "individualistic method" of producing power. That this is a movement in the right direction all engineers are agreed.

It is only by opening up new fields for the use of electricity and developing its application to each and all of the industries which produce the wealth of the country that the market for it can be extended and broadened and its cost as a marketable commodity further reduced to the consumer. In the present paper the author has attempted to indicate the advantages electricity has in the factory, and to show that if its installation is properly carried out that it is, in general, the best method of applying power. With a view to illustrating the underlying principles of power application, an industry of growing importance to India and to Scotland, the development of which is wholly due to British enterprise, and which is still almost wholly in British hands, will be described and the application of power to it considered.

* Reconstruction Committee, Coal Conservation Subcommittee on Electric Power Supply in Great Britain, April 16th, 1917.

THE SOURCE OF POWER.

As already indicated, the manufacturer has in regard to the power he needs two courses open to him :—

(a) To purchase power from outside suppliers.

(b) To produce power himself.

In regard to the first, in many parts of the country, notably in Lancashire, Yorkshire, Nottingham, Leicester and the woollen districts of Scotland, it is possible to purchase mechanical power under those "Room and Power" schemes which have done much for the starting of new industries in this country. In the case of a factory the author visited recently, some twenty manufacturers occupy one large building, buying room and power from the proprietor. Apart from "Room and Power" schemes, however, the only power it is open to the manufacturer to purchase is in the form of electricity. The decision of the manufacturer on this matter is in the main a commercial proposition governed by a comparison between the price at which power can be privately generated and electricity purchased. It should be affected, however, by important considerations, to which a commercial value can only be given with due regard to individual conditions. It can be claimed that the purchase of power leaves capital available for a more remunerative investment in manufacturing machinery; enables the management to concentrate its attention on the purely manufacturing side and permits of a gradual expansion of manufacture to meet demands, since all that is needed for such expansion is the purchase of further motors. This latter advantage was particularly noticeable in connection with the mobilisation of industry for munition purposes during the war. It is safe to say that without the adequate supply of electricity Great Britain had available, the steady growth in the manufacture of munitions which was so necessary to the success of the war could not have taken place. It is stated that 95% of the new factories put down for the manufacture of munitions were electrically driven.

The further important point may be made in connexion with the public supply of electricity that there is, as has been pointed out, a steady tendency towards the taking of power from central power stations, and that as the load of these stations grows in amount and diversity,

their generating costs are certain to fall. The cost of coal per unit generated is only one of the items affected by an improved load factor, and it was shown recently that an increase in load factor in a Dutch station of from 40% to 56% would reduce the coal consumed per Kelvin from 1.87 to 1.7 lbs.

It need scarcely be pointed out before leaving this part of our problem that the merits or demerits of Electrical Driving are not determined by a decision as to the purchase of power. The manufacturer who decides to make his own power can convert that power into electricity for power distribution throughout his factory.

Electricity for public supply purposes is in general distributed at high pressure for large industrial loads and at low pressure only for lighting and small industrial applications. For distribution to the motors in the factory it is usually reduced to a moderately low standard pressure such as 500 volts. This is done by means of static transformers which are sometimes placed in a sub-station from which a number of mills are supplied, or more generally separate transformers are provided for each factory. It should be pointed out here that some public supply companies in India so arrange the terms on which they supply current as to offer strong inducements to manufacturers to avoid the installation of transformers and apply high tension current direct to the motors. This is a practice which in general cannot be too strongly deprecated. High tension motors suffer from several drawbacks where ordinary industrial power applications are concerned. They have perforce to be of large size since small motors cannot be built for high pressure, while because of the element of danger attending their use it is not always possible to place them in the best position from a driving point of view. These disadvantages tend to nullify the flexibility in application of electricity for driving, which, in the author's opinion, forms its greatest claim to consideration.

A practice also that appears to be developing in India in connexion with the public supply of electricity is the undue penalising of the manufacturer if the power factor of his installation fails to reach a certain figure. This clause in electricity supply contracts is working out in practice in a manner that the supply engineers can scarcely have anticipated. The manufacturer, knowing that he is liable to suffer

a. severe penalty if not to have his power cut off if his power factor does not reach the value fixed by the supply company and being informed that large motors have a higher power factor than small motors and high speed motors than slow, is induced to put down large and frequently high speed motors. This again destroys flexibility and operates against the use of motors of a sufficiently low speed to be direct coupled to line shafting.

A more general adoption throughout India of the system in use in Calcutta is desirable, by which the reduction in power costs that would accrue to the supply company from an increase in power factor is calculated, and the greater part of the saving is credited to the consumer in the form of reduced charges, a corresponding provision being made for an increased charge for a low power factor. The author is informed that under the arrangement now in force it would pay a customer to instal apparatus to raise his power factor since by so doing he would get a reduction in current charges that would pay a dividend on his investment. Without such an equitable contract the supply company stands to gain and the manufacturer to lose by a too rigid adherence to standards which may militate against good engineering. Any restrictions that tend to make the application of electricity less flexible tend to make its adoption less rapid.

Apparatus to improve power-factor may be installed in the central power station or in the factory itself, preferably in the factory, which is the seat of the trouble. The following are the more usual methods of improving power-factor :—

- (a) Static condensers.
- (b) Synchronous Motors.
- (c) Synchronous Asynchronous motors.
- (d) Phase-advancers.

When the manufacturer decides to put down his own power plant he has in practice three types of prime-mover to choose from :—

- (1) The modern reciprocating steam engine.
- (2) The steam turbine.
- (3) The Diesel or the semi-Diesel engine.

Neither the Diesel nor the semi-Diesel have even in India in close proximity to the oil fields made much progress in industry. This is perhaps due to the comparatively large load furnished by individual mills, the expert attention required by

this class of engine, and no doubt also to the speculative nature of the price of oil.

The development of fresh oil-fields, a greater steadiness in the price of oil or improvements in the engine may lead to its greater employment. The author sees no reason to anticipate such a development, however, and feels that any cheapening of the price of oil would lead rather to its use as a fuel for steam boilers for which purpose it is finding a considerable outlet at present.

The real fight for supremacy in mill-work lies between the reciprocating steam engine and the steam turbine. The steam turbine is smaller and lighter than the reciprocating engine ; it can be housed in a smaller building and requires lighter foundations than its rival ; its first cost is lower, and assuming that a good vacuum is maintained, and that the size of unit is not too small, its power costs are lower also. It is, however, when we come to the principles that should underly the application of power that the most signal advantages of the steam turbine begin to appear. The turbine being a high speed rotary engine instead of a slow speed reciprocating engine, provides a turning torque on the shafting which is without cyclic variation ; a fact which contributes very largely towards the attainment of high standards for speed variation and cyclic regularity through the factory system. Taken in conjunction with the other factors mentioned, it has led to the growing adoption of the steam turbine as the prime mover for private installations. It should be generally recognised, also, that so far as power production on a large scale is concerned, the steam turbine is supreme in all cases where water power is not a serious competitor. Its almost universal adoption by central station engineers whose business is the maintenance of a reliable supply of power at a low cost, may be taken as a clear indication that it has proved itself to be the most satisfactory prime-mover and, in the author's view, its exclusive adoption for all factory installations exceeding 1,000 kw., when power is not purchased, is only a matter of time.

THE PRINCIPLES OF POWER APPLICATION.

It cannot be too clearly emphasised that the production of a manufactured article of a quality and at a price to compete is the primary if not the only objective of the

manufacturer, and that power is only one of the many agents he employs to secure this end. With this in mind, the following broad principles may be laid down as governing its application :—

- (a) The building requirements for power purposes must be little, if at all, in excess of those required by the manufacturing processes.
- (b) There must be no interference with the lay-out of the manufacturing plant to suit the manufacturing processes, lighting, accessibility and supervision.
- (c) The power equipment must be reasonable in first cost and in running costs, and finally,
- (d) It must be possible to secure the maximum production from the machines :—
 - (1) By ensuring reliable running.
 - (2) By maintaining the average speed of the machines within the recognised limits.
 - (3) By keeping the cyclic variation in speed of the shafting within defined limits.
 - (4) By facilitating prompt starting in the case of machines that start and stop frequently.

These are the basic principles that it is now recognised should govern every application of power to industry, and it may be said at once that the engineer can to-day satisfactorily meet each one of them, and that no reason exists on engineering grounds for any departure from their rigid application. When we proceed, however, to deal with matters quantitatively, we find these are affected by :—

- (1) External conditions, such as climate, etc.
- (2) The nature of the manufacturing processes ; and
- (3) The peculiarities of the machines to be driven.

Power requirements are affected by humidity and by temperature, which, by altering the tension of ropes, belts and spindle driving bands in textile installations and the viscosity of the lubricating oil, seriously influence the power required and, indirectly, the speeds of the machines. This effect is most serious in the morning and after week-end stops, and in India is particularly noticeable during the Monsoon, when, occasionally, the increase in tension of the

driving ropes and bands produces a load with which the engines have difficulty in coping.

The nature of the manufacturing processes and of the particular machines employed also influence to a marked degree the limits of speed variation it is desirable or practicable to lay down.

Speed limits that would be reasonable in a textile factory where the material runs through continuously could not be obtained in a tannery where separate hides have to be successively passed through the machines, nor would it be possible to obtain that degree of regularity in the driving of a mangle or a loom that might reasonably be anticipated with a ring or a flyer frame.

As regards the first requirements governing the application of power little comment is needed. Any excess in building specially required for power generation or application means additional capital expenditure, not directly remunerative. This may become serious if, for instance, large motor alleyways are insisted on, and in cases where only a limited space is available the productive capacity of the manufacturing plant may be seriously reduced.

With regard to the layout of the manufacturing plant, this should be carried out on the lines that best suit the manufacturing process and economical production. It is, for instance, in general desirable that, so far as possible, the raw material should enter at one end of the building and pass through without interruption to the packing and forwarding departments. The driving system should permit of this being done and should not, in any way, by reason of shafting requirements, etc., interfere with the internal economy of production.

The older mechanical drives where heavy bevel gears and other mechanical transmission devices were employed did interfere, to a serious extent, with factory layouts, and prevented the adoption of arrangements best suited to manufacturing conditions.

The equipment for driving, also, must not be excessive in first cost, because here, too, it should be noted that any capital expended on ancillary machinery, such as the power equipment really is, is capital that could be usefully employed on the productive side.

The requirements we have just been considering are intended to secure that the maximum amount of productive plant is obtained from the capital available, and

FIG. 1.—Layout of Shafting in Weaving Shed (Bombay).

we have now to consider how far the maximum production can be obtained from the manufacturing plant actually installed. This is secured, in so far as it depends on the power plant and transmission system, by having a reliable installation not subject to stoppages and by securing that as steady a speed as possible is maintained throughout the factory.

Where a steady running prime mover drives directly a machine which does not provide a cyclic variation in load, the speed of the shafting and transmission system generally should be perfectly uniform. In no system, however, is it possible to secure such uniformity, and it becomes necessary to consider what variations occur and within what limits those variations can be kept. The variations usually met with arise from three causes—

(a) Irregularity in turning movement of the prime mover.

(b) The starting and stopping of individual machines on a line shaft.

(c) Cyclic variations in torque of individual machines.

The effects produced by irregularity in turning movement of the prime mover are two-fold—

(a) Variations in average speed of long period due to variations in load, or to poor governing.

(b) Cyclic variations due, for instance, to reciprocating moving parts.

Governing and regulation have been so far improved that it is now possible to maintain the average speed of an engine within sufficiently fine limits, and the real trouble in factory drives is found to arise from rapid fluctuations in speed which are superimposed on the average speed. These speed fluctuations, which are generally of high frequency, are commonly referred to

FIG. 2.—Tachograph readings in Weaving Shed (Bombay).

FIG. 3.—The Effect of Cyclic Variation in Speed.

by mill engineers under the heading of "cyclic irregularity."

It may be desirable at this stage to consider permissible limits for speed variation based on experience of what can be obtained and is obtained in practice in textile work. A short time ago in a series of articles* published in the *Textile Recorder*, a writer, evidently with experience, maintained that with modern systems of governing and regulation, it should be possible to keep the speed variation of a reciprocating steam engine within 1% and $1\frac{1}{2}\%$, and that a variation beyond $1\frac{1}{2}\%$ to 2% should not be tolerated. He found that at the driven end of the first motion shaft the speed variation had usually increased to a much higher figure, such as 5%, but

that it should be possible to design the layout so as to keep it below 3% at this point and that a higher figure should not be permitted. Proceeding now along the shaft from the driven end he found a steady increase in speed variation until at the extreme end figures varying from 9% to 17% were reached.

It was found, however, that when the speed variation at any point exceeded $6\frac{1}{2}\%$, the effect on the spinning was distinctly noticeable and weaving on automatic looms was impossible. This writer, therefore, gave $6\frac{1}{2}\%$ as the maximum permissible speed variation that should be allowed in any part of a textile mill.

The figure was clearly what the writer felt he could hope to obtain in a mechanically driven mill, and the fact that he was willing to permit of a speed variation, the harmful

* *Textile Recorder*, Manchester, Feb. 15, 1911, to Feb. 15, 1912

effect of which was noticeable on the machines, was clearly because he had little hope of obtaining better results in mills driven on the older systems. Tests the author took in India in a good factory have shown that a speed variation of 1% near the engine became $3\frac{1}{2}\%$ at the beginning of the furthest loom shaft, 9% at the middle of the shaft and 14% at the end. Fig. 1. shows the lay-out of the shafting in this factory and indicates the points at which the readings were taken, while Fig. 2. shows a photographic reproduction of the actual readings themselves, the small vertical scale divisions corresponding to a speed variation of 1% and the distance between the horizontal points corresponding to three-quarters of a second or six seconds over the scale. The difference in the speed variation at points 3 and 3a is specially to be noted, and also the rapid increase in speed variation at 3b and 3c. The author ventures to say that at no part of a mill shafting system should the speed variation exceed 3% to 5%, and he looks forward to the day when every industrial power system will be tested and passed for speed variation on a standardised basis, to limits such as these, before being taken over.

The effects of speed variation as shewn by experiments are that when it exceeds a certain limit some machines cannot be run at all, the production of other machines, and in particular of spinning machines, is affected through breakages, and the production of all machines is reduced below the maximum of which the machines are capable for reasons that will be clear from the diagram shewn in Fig. 3. The first curve, I, in this diagram shows a speed variation of 14%, giving an average speed of 93% or 7% below the maximum speed attained. The second curve, II, illustrates an attempt to improve the drive and shows a speed variation of 6%, giving an average speed of 97% or only 3% below the maximum. The fall in average speed illustrated by the first curve represents a direct loss in production of 7%, and is a feature of speed variation, to which all too little attention is given. The same remark applies to the progressive character of the speed variation from the engine to the extreme end of the most remote line shaft. From a manufacturing point of view the rapid oscillations of shafts which result in the speed variations, we are now considering, are more

serious than the slow variations in average speed to which reference was made earlier, and are produced in the main by the starting and stopping of machines and by the irregular torque of individual machines. For a given thickness of shaft they are less with fast shafts than with slow and with short shafts than with long. They are, on the other hand, stimulated by any cyclic variation of speed of the prime-mover.

The author believes that many of the mistakes made in connection with the application of power to particular industries are due to a lack of knowledge on the part of those making the application, of the processes employed, and of the peculiarities of the machines used and to a lack of appreciation also of the needs of the industry and of the personal equation of those employed in it. He feels, therefore, that he need offer no apology for entering in some detail into these elements, choosing for this purpose an industry which furnishes problems to the power engineer typical of those he is likely to meet with in most textile industries and in many industries of a similar character.

THE JUTE INDUSTRY.

Close on 90 per cent. of the world's jute is grown in the Presidency of Bengal, the principal supply coming from the northern and eastern belts. Behar and Orissa come next as a source of supply, followed by Assam, a small contribution being made by the State of Cooch Behar.

The output of raw fibre for the past 20 years has varied from $6\frac{1}{2}$ million bales to $10\frac{1}{2}$ million bales per annum, the latter record figure being reached in 1914. This is sold at a price which fluctuates considerably, varying during the war for instance, from Rs. 35 to Rs. 75 per bale. For statistical purposes it may be taken at an average of Rs. 50 per bale.

Somewhat less than one-half of the jute crop was exported in a normal pre-war year, the United Kingdom taking about one-third of the exported raw material, Germany about one-sixth, the United States somewhat less and the bulk of the remainder being divided between France, Australia, Italy and Spain.

It will be clear from the foregoing that the centre of gravity of the world's jute industry does not lie far from the city of Calcutta. The natural tendency to manufacture as closely as possible to the

source of the raw material aided largely by circumstances created by the war such as increased freights, etc., is bringing the centre of gravity closer still. This will be clear when it is realised that the consumption of jute in Indian mills is now more nearly two-thirds of the total crop than one half as formerly, giving employment in 1918 to 270,000 persons engaged in handling the raw material and in some 80 mills equipped with over 800,000 spindles and some 40,000 looms. This represents a truly remarkable development when one remembers that the first spinning mill was put down in India as recently as 1855 and the first weaving shed in 1859 some 20 years after the manufacture of jute had its first beginnings as a machine industry in Dundee.

Deccan hemp or Bimlipatam jute as it is sometimes called is a plant similar to jute and is grown in Madras and Bombay. About half of the crop of this plant, which before the war did not exceed 400,000 bales per annum, is exported, the remainder being manufactured in three Madras mills almost wholly for Indian consumption.

JUTE, PREPARATORY PROCESSES.

Jute is a bast fibre and as is the case with all vegetable fibres obtained from the stems as distinct from the leaves of plants it is found on the outside of the stalk of the plant and attached to it by a gummy substance. It is usually sown in the months of March, April and May, reaches a height of from 10 to 12 feet and is cut, not pulled as in the case of the flax plant, before it reaches maturity in the months of July, August and September and in some cases, in October. The plant is placed when cut in running water or in retting ponds for some 10 to 12 days or longer. When the process of retting is complete the fibre is easily separated from the woody stalks by hand or by treatment with a mallet. Power is not employed for the cutting of jute though it is possible that experiments now being carried out with a view to providing a suitable machine for pulling flax may, if successful, have a bearing on the cutting of the jute plant.

The fibre after retting and separation from the stem of the plant is made up loose or in bales and despatched to Calcutta to the mills or to the press houses for re-baling for export purposes. Loose jute is made up either in drums or in what are

known as "kutchha" bales weighing, if hand pressed, $1\frac{1}{2}$ maunds, and if power pressed, $3\frac{1}{2}$ or 4 maunds each; sometimes for local transport and always for export, it is made up in power pressed "pakka" bales of 10-2/5ths cubic feet capacity and weighing 400 lbs.

JUTE, MANUFACTURING PROCESSES.

The jute as received at the factory, is stored in a warehouse from which it is taken to the jute opener or crusher.

OPENER OR CRUSHER.—This machine breaks up the material of the bales, jute from a number of which is fed on to it at once and also gives the jute a preliminary softening. The machine is usually run from 115 to 120 r.p.m. and requires some 3 to 4 horse-power to drive. After the jute has passed through the opener it is made up in "streaks" of a uniform weight by the batchers who also remove any inferior fibres and these "streaks" are fed on to a machine called a softener.

SOFTENER.—The softener is provided with a series of rollers which may be fluted or straight and during its passage through this machine warm water and oil are fed on to the fibre. Where hand batching is employed, the water and oil are added to the jute after its passage through the softener. The object of the process is to soften the fibre and improve its spinning qualities. Softeners vary in size depending on the number of pairs of rollers usually from 31 to 79 and the speeds recommended by the different makers vary from 135 to 145 r.p.m.

For estimating purposes from $3\frac{1}{2}$ to 7 pairs of rollers per B.H.P. may be allowed, softeners with a small number of rollers taking a proportionately larger power than those with a large number of rollers. It should be noted that these machines may occasionally be heavily overloaded for a short period to as much as 60% in excess of the normal load. A jute softener has by law to be provided with an automatic knock-off motion which comes into operation if the operative is accidentally dragged forward by the feed. After passage through the softeners the fibre is stacked for over 24 hours with a view to the more thorough distribution of the oil and water throughout the mass; the fibres are then usually cut by hand and transferred to the preparing department where the resulting "streaks" are placed on the first machine in that department, viz., the breaker card.

BREAKER CARD.—This machine does for the coarser long vegetable fibres like jute and for tow, etc., what is done by a more expensive heckling and spread board or gill box treatment for the finer long vegetable fibres, i.e., it converts them into a long smooth band known as the "sliver." These machines, the cylinders of which are generally 4 feet in diameter with a 6 ft. face and occasionally 5 ft. in diameter with a 6 ft. face, may run at from 175 to 210 r.p.m., the horse-power varying from $4\frac{1}{2}$ to 6 B.H.P. The starting torque is high and the load is not always evenly distributed among the machines installed.

In order that uniform yarn may be produced the feed to the machines has to be controlled at some stage in the process of manufacture. This is usually done by weighing the feed to the breaker card and distributing it over a measured length of feed lattice. It may, however, also be done after the sliver has left the Breaker card by passing it into a balling or lap machine.

BALLING OR LAP MACHINE.—This machine takes a number of slivers from the breaker card and converts them into "laps" of uniform weight for a given length. It is usually run at 300 r.p.m. and takes approximately 1 H.P. to drive. The sliver from the breaker card, or if a balling machine is employed, the "lap" from this machine is placed on the feed of an intermediate or a finisher card. The designs of the breaker, intermediate and finisher cards are generally similar and the first and last are as a rule alone employed in Bengal while on the other hand intermediate cards are common in Dundee.

FINISHER CARD.—The finisher card carries on the work from the breaker card or the intermediate card as the case may be, cleans the fibres and renders them more parallel. The speed of the finisher varies from 160 to 220 r.p.m. and the power from 3-4 H.P., being less than that required by the breaker cards. The sliver from the finisher card is also dispatched in a sliver can and from this can is fed to the first drawing frame.

FIRST DRAWING FRAME.—Several slivers from the finisher cards are combined and pass through the drawing frame together, being elongated, rendered more parallel, and converted into a sliver more regular in weight per unit length. Drawing frames are designed on different principles, the more

common being "push bar" and "spiral" drawing, the former largely used for first drawing frames and the latter for second drawing frames. The speeds of these machines vary from 160 to 300 r.p.m., the push bar drawing frames usually running at a higher speed than the spiral frames. The horse-power depends on the number of delivery heads, which are found to vary from 2 to 8, there being usually from 4 to 8 slivers per head. Two heads per horse-power is a safe figure on which to estimate. "Spiral" drawing requires less power than push bar drawing. From the first drawing the sliver is transferred to the second drawing frame.

SECOND DRAWING MACHINE.—The particulars of this machine are generally as for the first drawing, several slivers being usually run into one as in the case of the first drawing. From the second drawing frame the sliver may be passed on to a third drawing frame of similar design or as is more usual in Bengal to the roving frame, which is the last machine in the preparing department.

ROVING FRAME.—In this machine a slight twist is, for the first time, given to the sliver in order to permit it to be further drawn out. The roving frame consists of spindles and flyers placed in front of a set of drawing rollers. The speeds of roving frames vary from 200 to 215 r.p.m. the spindle speeds being generally three times this. The number of spindles per frame varies from 40 to 72, and 12 to 16 spindles may be taken per horse-power. From the roving frame the product is passed on bobbins to the spinning frames.

SPINNING FRAME.—The dry spinning process is almost invariably employed in jute, wet spinning being reserved for the finer classes of long vegetable fibre such as flax, etc. The frames employed are invariably flyer frames, the flyers of which are positively driven, the bobbins running loose under the control of a drag weight. The traverse of the bobbins varies from 3 to 5 inches, the corresponding spindle speeds varying from 4,000 to 2,000 r.p.m. The spindles are driven by tapes passing round a cylinder and driving on to wharves on the spindles. The machines usually have two sides the number of spindles per side varying from 64 to 80. The tin drum speeds vary from 400 to 570 r.p.m. There is a variation in the power taken during the traverse of the bobbin, involving a variation

FIG. 4.—Individual Electric Drive for Roving or Spinning Frames.

FIG. 5.—Individual Electric Drive of Dressing Machines (Dundee).

between the top and the bottom positions of some $12\frac{1}{2}\%$, the power being greatest when the carriage is at the top. This is due to the unmechanical nature of the drive provided by the tin rollers. This variation is reduced to some $7\frac{1}{2}\%$ by a patent auxiliary tin roller drive that has recently been introduced, which has also had a remarkable effect on the power consumption. The following test figures may be of interest:—two frames with the old single cylinder drive gave respectively 12.2 and 11.7 spindles per B.H.P., a frame of the same dimensions and to the same particulars but with the auxiliary cylinder drive and running at a slightly higher speed, but it is worthy of note at a slightly lower tin drum speed thus showing less slip, gave 16.5 spindles to the horse power, a remarkable improvement in efficiency. The makers claim rather a higher saving than this but these figures were actually obtained in independent tests. This drive, either in the patented form or some variation of this, is in fairly general use.

We have now jute yarn which depending on the class of fibre selected and on the adjustment of the preparing and spinning machinery described, is suitable either for "warp" as the threads which run through the length of a woven fabric are collectively termed, or for the "weft" which "crossing and interlacing" with the warp makes up a jute or part jute fabric. Whether intended for warp or for weft, if the yarn when it leaves the spinning frame has to be sent to a distance or sold it is made up into "hanks" on a reeling or hanking machine. Hanks are made up of a uniform weight depending on the counts of the yarn, and after leaving the hanking machine are sized and made up into bundles in a hand operated bundling press. The hanking reel is sometimes driven by hand but is more usually power driven. The *Power Hanking Machine* is usually double sided and capable of making from 12 to 24 per hanks per side. Such a machine running at 75 r.p.m. and having 20 hanks per side, was found to take .6 H.P. When the thread is intended for warp yarn it is generally wound from the spinning bobbins into rolls or "cheeses" the contents of a number of bobbins being absorbed in one roll. This is also done when hank yarns have to be twisted, sized or otherwise treated. The operation is carried out on a *Roll Winding Machine*. This machine runs at about 240 to 400 r.p.m. and is

usually double sided with from 20 to 70 spindles per side. A usual power allowance is 24 spindles to the horse power.

Weft yard is prepared for the loom in two alternative ways, viz., by being wound as cops generally from $1\frac{1}{2}$ " to $1\frac{3}{4}$ " in diameter and 8" x 12" long or by being wound on pirns. Cops are placed direct in the loom shuttle, the thread being unwound from the inside and are now almost universal in jute weaving. A *Cop Winding Machine* is usually double sided with 45 to 60 spindles per side and runs at from 250 to 440 r.p.m. The spindle speed for $1\frac{1}{2}$ " x 2" cops is about 800 r.p.m. and for $1\frac{3}{4}$ " x 1.6" cops about 1,000 r.p.m. and the number of spindles to the horse power varies from 16 for the larger bobbins to 20 for the smaller. A *Pirn Winding Machine* takes about the same power but runs about 180 r.p.m.

We have now to deal with the warp rolls or cheeses already referred to and which have to be converted into the long band of threads known as "warp." For use in the loom also the warp has to be beamed, viz., wound on to the weaver's beam or beams which are found at the back of every loom.

In most cases and particularly for the better class fabrics the warp threads before being wound on the weaver's beam are sized or "dressed" as it is termed. Dressing has many advantages, it improves production in the spinning department as less twist is needed for dressed yarn; it reduces waste and facilitates weaving. Dressing is now almost universal in the jute industry, the use of the dry, or "green" warps being very limited.

There are many methods employed for preparing warp yarn for the loom. Four distinct methods each with its own manufacturing variants are to be found. The author is, however, only concerned with noticing the machines in common use so that the problem of driving may be more readily considered and will therefore confine himself to the more general systems of jute warping and beaming.

In all systems a number of warp rolls or in some cases where roll winding is not employed, bobbins direct from the spinning frames are placed in a creel or bank generally of V shape and capable of carrying anything from 40 to 500 spindles depending on the system adopted. From this bank or creel the yarn if it is not to be dressed passes to a *Beaming Machine*.

A dry yarn beaming machine may be single or double, viz., it may be fed from one creel or from two creels one at each end; it may also be with or without drawing rollers. The speed of these machines is about 80 r.p.m. and the H.P. from $1\frac{1}{2}$ to 2 B.H.P.

Where jute warps are dressed the complete operation of dressing, warping and beaming is carried out in a single machine called a *Dressing Machine*. This machine is provided with steam heated cylinders, and has either one set of two cylinders, two sets of two cylinders, one set of three cylinders, or two sets of three cylinders. The machines usually run at about 450 r.p.m. and the more common widths are 60" and 72", the power varying from 3-3 $\frac{1}{2}$ B.H.P.

Where warps are manufactured for sale a new method of warping is finding application, particularly in Dundee, viz., link or chain warping. The *Linking Machine* so called, which was introduced from the cotton trade, consists of the usual bank or creel, a leasing apparatus, a measuring machine and the linking machine proper. The linking and the measuring machine alone are power driven. They are mechanically coupled together and driven as one machine absorbing about 1.5 B.H.P. In some machines two warps may be linked at once or one only may be dealt with.

Instead of converting the warp into a chain by the process just described, it may be passed into a machine called a *Ball Warping Machine*, which delivers the warp wound on a series of rollers not unlike "cheeses" but larger. This machine takes approximately .5 B.H.P. to drive. Whether prepared in the linking or in the ball warping machine, the warp has to be put through a beaming machine, in some cases after being dressed and in other cases in a "green" condition.

(To be continued.)

OBITUARY.

SIR RICHARD VASSAR VASSAR-SMITH, Bt., D.L.—Sir Richard Vassar-Smith, Chairman of Lloyds Bank, died at his London residence, 16, St. James's Street, on August 2nd. A son of Mr. Richard Tew Smith, of Wotton, Gloucester, he was educated at the local College School, and began his successful business career in his father's firm of agents and carriers to the Great Western Railway, becoming head of the concern at the age of twenty-seven. He assumed the additional name of Vassar by Royal Licence: When, in 1889, Lloyds Bank absorbed the Worcester City and County Bank, of which he was a director, he joined the board of the

former and was appointed to the chairmanship in 1910. The numerous public positions he filled at different times included those of President and Chairman of the Council of the Bankers' Institute, Chairman of the Committee of the London Bankers' Clearing House and Chairman of the Central Association of Bankers. Throughout his busy life he took an active interest in the affairs of his native county, the Gloucestershire Territorial Association, for instance, owing much to his support. He was also a member of the Council of Cheltenham College, Chairman of Council, Cheltenham Ladies' College, and Chairman of the Council of St. Hilda's Colleges, Oxford and Cheltenham. His baronetcy, conferred in 1917, was a well-deserved recognition of the valuable services he rendered to the country, especially in connexion with the great banking institution he so ably controlled. Elected a Fellow of the Royal Society of Arts in 1919, he was a member of the Council for twelve months.

RICHARD WILLIAM CROWTHER, F.S.A., J.P.—By the death, on July 21st, in his seventy-fourth year, of Mr. R. W. Crowther, Chairman of Messrs Sewell & Crowther, Ltd., the Society loses an old and respected member; he was elected as long ago as 1881. Mr. Crowther took an active and useful part in the public affairs of Stoke Newington, where he resided, and when Alderman Sir John Baddeley became Lord Mayor of London, succeeded him as Chairman of the Stoke Newington Justices.

MALAYA'S NEW POTTERY INDUSTRY.

Because it represents an entirely new industry to Malaya, the formal opening of the pottery works at Gopeng was made the occasion of somewhat elaborate ceremonies. The plant, which is situated about 16 miles from Ipoh, is equipped to handle all the processes from refining the crude clay to the decoration of the completed piece.

According to a report by the United States Consul at Penang, casting and jolleying are the processes used, permitting a comparatively large output with labour that is not yet thoroughly trained. Teapots, jugs, ewers, and basins are already being turned out, notwithstanding that a few weeks ago the Malay girls employed in the casting room had never seen a pottery. As the available labour becomes more skilled the production of porcelain ware in bulk is contemplated.

All the materials required for pottery making are found within 3 miles of the works. Besides supplying its own clay requirements, the company ships china clay to cotton mills in Bombay and paper mills in Calcutta. The barrels for packing the product, it may be mentioned, are made at the works.

The establishment of this new industry in Malaya has aroused widespread interest.

PROCEEDINGS OF THE SOCIETY.

TWENTIETH ORDINARY MEETING.

WEDNESDAY, 26TH APRIL, 1922.

SIR JOHN F. C. SNELL, M.Inst.C.E.,
Chairman of the Electricity Commissioners,
in the chair.

The paper read was:—

THE USE AND ADVANTAGES OF ELECTRIC POWER IN THE FACTORY, AS ILLUSTRATED BY ITS APPLICATION TO THE JUTE INDUSTRY.

By J. F. CROWLEY, D.Sc., B.A., M.I.E.E.

(Continued from page 676.)

THE LOOM.—The next operation with which we have to deal is that of weaving which is carried out in a loom which may vary in reed space—roughly corresponding to the maximum width of cloth—from 30" to 156". As a rule jute looms are of the plainest description, dobbies being very seldom fitted and jacquards being used only for the making of jute carpets and similar goods, the manufacture of which is, however, a separate industry.

The jute loom has certain special features which distinguish it from a power point of view from other looms. In the first place the crank-shaft is set unusually far back from the front of the loom to allow of a larger movement of the "lay" to accommodate a large shuttle and to provide extra space for the harness.

A jute loom also requires a high starting torque usually 2-2½ times normal torque, and has a particularly irregular power cycle as may be seen from the torque curve illustrated in Fig. 6. This curve which the author

FIG. 6 -- Cyclic Variation in Torque of a Jute Loom

FIG. 7.—Group Electric Drive with Chain Transmission (Dundee).

believes to be the first such curve published, was taken on a loom driven by an individual electric motor and may be taken as representing the cyclic variation in torque of a standard jute loom. It will be noted that the loom is actually returning energy to the driving system during part of the cycle. The speeds of looms vary from 90 picks per minute to 180 picks per minute, depending on the reed space. The average power taken by a group of looms, allowing the usual load factor for weaving sheds varies from .5 B.H.P. to 2 B.H.P. per loom. The load factor or weaving efficiency of a jute shed varies from 45% to, in the very best cases, slightly over 70%, depending on the class of material woven, the type of operative, etc.

If the material woven is not of a sufficiently fine quality to require mangling, it is delivered to a *Damping Machine*. These machines generally run at 140 r.p.m. and take approximately 1 to 1.5 B.H.P. to drive. After the cloth has been damped it is passed on to a calendaring machine.

CALENDER.—This machine consists of a number of pairs of rollers, the centre roller being heated by steam and varying degrees of pressure are maintained on the rollers by means of weights on a lever system. The cloth may be passed singly between the rollers when what is known as a "flat" finish is imported to it or it may be wound on to one of the rollers for a "chest" finish. The first treatment is the more usual and for that treatment the calender revolves continuously in the one direction; for a "chest" finish on the other hand, the calender reverses its direction of rotation periodically.

All calenders, except those arranged for individual electric drive, are provided with a straight belt and a cross belt drive from the line shaft and a clutch that can be engaged with either of the two driven belt pulleys to enable the direction of rotation to be reversed. A reversing motion is required by law to be fitted to all jute calenders. In the front of the calender is a small winding off roller which is usually provided with an auxiliary drive. The usual sizes of jute calender are 96" and 132", the horse-powers generally allowed being 15 B.H.P. and 20 B.H.P. respectively. It should be noted that these machines have an abnormally heavy starting torque.

If a high-class finish is required, the material is treated in a mangle instead of

in a calender; in this case before being damped the material is passed through a *Cropping Machine*, which is generally 72" or 96" in width and takes from 5 to 6 B.H.P. to drive; depending on the width and on the number of spirals on the machine. After being cropped and damped the material is passed on to the mangle.

MANGLE.—A mangle is a much larger and heavier machine than a calender, and works with a much higher pressure between the rollers, usually varying from 40 to 120 tons, and produced hydraulically. The method of operation consists of winding the cloth to be mangled completely on to one roller, the cloth being pressed between this roller and another. The operation of the machine is reversed about every 6½ seconds, the cycle of operation being as given in Fig. 11. The complete operation of mangling requires about 11 minutes, but varies somewhat with the material. The arrangement for reversing the mangle is mechanical and consists of clutches of the expanding crown type, put in and out of operation by an auxiliary mechanism worked from the line shaft; the usual widths of mangles are as in the case of calenders 96" and 132". The horse-powers usually employed for individual driving are 55 B.H.P. for the 96" and 70 B.H.P. for the 132" size.

The length of the cloth produced on the loom is measured by a *Measuring Machine*, which takes from 1 to 1.5 B.H.P. to drive. It can be "crisped" or folded double on a *Crisping Machine*, which takes about the same power as the measuring machine and made into rolls by a *Rolling Machine or Calenderoy*, which also absorbs about the same power. The measuring, crisping and rolling may be carried out in one operation, in a combined machine when the power required is about double that for one of the single machines.

If the material is to be made into sacks or bags, it is cut to the correct size in a *Sack Cutter*, which may be hand or power driven and if the latter absorbs from 1 to 1.5 B.H.P. The sewing of these sacks is done on a strong type of *Sewing Machine*, which takes from .12 to .25 B.H.P., and *Hemming Machines* also are employed, taking about .12 B.H.P.

Among other machines that may have to be driven are the *Root Opener* which takes about 8 H.P.; the *Waste Cleaner or Dust Shaker*, from 1.5 to 3 H.P.; the *Teaser* from 4 to 4.5 H.P.; the *Mixer*, about 5 H.P.; and

FIG. 8.—Individual Electric Drive in Weaving Shed (Calcutta).

FIG. 9.—Individual Electric Drive of Damping Machine (Dundee).

the *Twister*, usually of the flyer type and largely used for doubling yarns. With dry spun yarns like jute, the twisting may be done from the spinning bobbin or the yarn may first be wound upon longer bobbins or spools. The bobbins range from 2½" diameter, 4" traverse, to 6" diameter, 10" traverse, the pitch from 4" to 9" and the spindle speeds from 1,100 r.p.m. to 2,500 r.p.m. The pulley speeds are generally slightly less than those of the corresponding spinning frames. A frame of 4" pitch would require about 1 H.P. for every 14 spindles and a frame of 5" pitch 1 H.P. for every 12 spindles.

Provision has also to be made for the drawing of the *Hydraulic Press Pump*. This generally consists of 8 rams, and takes from 45 to 50 H.P. to drive. The cyclic variation in torque is high when the pump is operating at high pressure since in this case it is usual to employ four only of the eight plungers. When operating at low pressure on the other hand the torque variation is not considerable.

As a rough guide to the total power requirements of a complete jute mill and its associated factory—the name mill it should be mentioned, is usually applied to the preparing and spinning departments, and factory to the weaving sheds—it may be said that for the preparing, spinning, weaving and finishing departments, from 3¼ to 3½ H.P. per loom has to be provided depending on the class of goods handled and on the degree of finish imparted.

It will be found that the power taken by individual machines in any department of a mill varies with the quality of the fibre employed, the speed at which the machines are driven and with the manufacturing efficiency of the department, which determines the number of machines running at a given instant, and it will also be found that the machines of different makers require different powers to drive; subject to these qualifications the figures given furnish a fair indication of the usual power requirements. While based in most cases on actual tests they should be used only as a general guide and in no case should powers be based on them without due regard to the factors mentioned.

It need scarcely be said also that the particulars of the textile processes are given purely for the guidance of engineers, and are in no sense intended to be taken as having any authority from a textile stand-point.

THE DISTRIBUTION OF POWER.

We have so far considered the sources of power available to the manufacturer, the principles that should govern its application and the essential elements of the jute industry, from the point of view of the power engineer. We have now to consider the most suitable method of distributing the energy from the prime mover, through the factory, until it finds its application at the shaft of the driven machine. This distribution system may comprise one or many links, and these links may be wholly mechanical, electrical and mechanical, or wholly electrical.

MECHANICAL DISTRIBUTION.

In the early days of factory driving in Great Britain, it was usual to find a Boulton & Watt engine connected by spur gearing to line shafting, and this, in turn, driving the machines by means of leather belts, the additional shafting being driven by further gears, either plain or bevel. Owing to the irregular character of the drive produced, the power lost in transmission, and to the difficulty of suitably connecting various shafts—frequently at different angles to each other—together, this system is almost wholly replaced in modern mills by a rope transmission system from the flywheel of the engine. If such a system is carefully thought out in a factory suitably designed, it is probably the best mechanical distribution system for heavy powers. An example of a weaving shed drive comprising rope and bevel gears, is given in Fig. 1, where ropes from the flywheel of the engine drive the second motion shaft, which, in turn, drives the cross shafts through bevel gears. In general, a prime mover of slow speed and low output is connected to the line shafting by ropes, chains or belts of fabric or leather; and if of slow speed, but high output, by ropes or steel belts. Steel belts have been introduced on the Continent for heavy drives of a moderately slow speed, and appear to have given satisfaction. There has not, so far, been much experience in this country with them.

Where the prime mover is of high speed, as in the case of a turbine drive, if electrical transmission is not employed, it is usual to adopt a double helical self-contained single or double reduction gear connected through a coupling to the turbine shaft, for reducing the speed to one more suited to the ordinary transmission systems.

FIG. 10 —Individual Electric Drive of Jute Calendar (Dundee).

FIG. 11.—Type of Torque and Speed Curve of Jute Mangle.

FIG. 14.—Individual Electric Drive of Press Pump (Calcutta).

The slow speed shaft of such a gearing is then connected to the line shafting through ropes, chains or belts in the ordinary way. In India, where this drive has been adopted to a certain extent, it is not unusual to find the second motion shaft of the geared turbine connected through a flexible coupling to one of the heavier mill shafts, the remaining shafting only being driven through ropes. This system has the advantage of effecting a considerable saving in the power lost in transmission, in the case of the direct coupled shaft, but there is a distinct loss of flexibility as the turbine has, of necessity, to be lined up to the shaft, with which it has to be coupled, and this generally means placing it in an unsuitable position.

The whole of the power also is transmitted through the reduction gear, which is liable to be a source of weakness.

It is not intended to consider closely the merits of the different methods of mechanically distributing power, but the following points may be of interest. Belts, which form one of the earlier methods of drive, have still a definite function, particularly for the transmission of low powers. Indeed, through improvements introduced

by manufacturers and others, their position has recently been strengthened. The development, principally on the Continent, of the jockey pulley drive has extended the field for belt drives, which are now designed to cope with short belt centres, and exceptionally high pulley ratios.

If due attention is given to layout, rope drives should give satisfaction. The minimum diameter of pulley round which the rope has to pass should not be less than thirty diameters, if a reasonable rope life is desired. Driving centres also should not be much less than 20 feet for the larger powers, and the angle of drive should not, if possible, exceed 45 degrees with the horizontal. The efficiency of rope drives is not high, but the drive is more flexible, and more steady than can be obtained from gearing.

Chain driving has come to be recognised as a standard method of driving for moderate powers at ratios below 6 or 7 to 1. The drive is positive, being akin to machine cut gearing in this respect. It is, however, flexible in application, needs less aligning to shafting than gearing, and is, in practice, of at least equally high efficiency.

FIG. 12.--Individual Electric Drive of Jute Mangle (Dundee).

FIG. 13.--Power Record showing effect of Mangle Load.

Chain driving is particularly useful where it is found desirable to drive shafts from the centre with a view to keeping cyclic irregularity in speed within proper limits. Electric motors and chain transmission enable this to be done very satisfactorily, as may be seen from Fig. 7, which illustrates a drive of this kind.

ELECTRICAL DISTRIBUTION.

When electrical distribution is employed, a single large electric motor may be installed to drive the whole of a factory, occupying then the position that would, in a mechanical system, be occupied by the turbine, reciprocating engine or other prime mover. Instead of employing one large motor, a number of small motors can be installed to drive each machine on the principle known as the "Individual Electric Drive." The individual motors may be direct coupled to the machines, or drive through a simple transmission link as, for instance, a belt, chain or gear. Between these two systems lie the various groupings of shafting, which are designated "Group Electric Driving in Large Units," or "Group Electric Driving in Small Units," depending on whether the motors are large and drive a number of shafts, or small and driving only small groups of shafts. Just as there is no golden rule as to what transmission system should be employed, so is there no golden rule as to the system of electric driving that should be adopted. Each case has to be carefully considered on its merits, and in the light of experience gained in a similar class of work. Certain guiding considerations can, however, be laid down. In general, the installation of a single large motor, involving as it does the retention of a complicated mechanical power transmission system with its many defects, brings few, if any, of the advantages of electrical driving, and is not to be recommended, nor, indeed, is the unconsidered adoption of individual electric driving. While, undoubtedly, the ideal drive, where motors exist, as they now do in almost every case, suited to the work to which it is proposed to set them, individual drive is, in many cases, more costly than group drive. Where this is the case, its application should be confined to machines where it can be shown that its installation has a commercial advantage.

The dividing of the shafting into large or small groups is governed, to a certain extent, by the desire to reduce the lengths

of line shafting, in order to reduce speed variation or friction losses, and also by the nature of the processes carried on, which in some cases, require certain departments to be driven independently, on account of overtime and of separate power costing.

The principle of providing separately controlled drives for each department is not difficult to apply in a jute factory, particularly in India, where almost all the mills are on the shed principle, and the raw material from the godowns is, as a rule, arranged to enter at one end of the building, passing on through the successive departments until it reaches the baling-presses as a finished article.

Each department is generally driven by one or more line shafts, running parallel to each other across the full width of the building, there being some eight such shafts in a 500 loom mill, and a similar number of shafts, but of much less power, in the weaving shed. In a mechanically driven mill these shafts are usually connected by ropes, running in a rope race, to the engine. In arranging for the conversion of this type of mill, to electric drive, motors may be placed in the rope alley-way, and connected by belts to each separate shaft, as in Fig 15, or by ropes as in Fig 16, which illustrate two such conversions. Weaving shed shafts, which generally run at about 180 r.p.m., are best driven by chain, one motor being placed between two shafts and driving both, or, as in Fig. 7, one shaft only.

Electric motors may be placed at the ends of the shafts they have to drive, or in the middle. Placing them in the middle has the important advantage that cyclic variations in speed are very much reduced, but, on the other hand, the overhead view is interfered with, and separate steel platforms have to be provided to carry the motors. There is one important exception to this. The design of many Indian jute mills is such that it is possible and practicable, to place motors over the centres of the shafts they have to drive, connecting them to these shafts by chains, the motors themselves being suitably housed in a simple superstructure raised on the flat shed roof. If placed at the ends, the motors are in the clean atmosphere of the alley-way, but the speed irregularity of the shafts may be excessive, particularly if the shafts exceed, say 300 feet in length, as they do in many Calcutta mills where at least one shaft 700 feet long is installed. In general, it is

FIG. 15.—Group Electric Drive with Belt Transmission (Calcutta).

desirable to drive weaving shed shafts which are light, subject to considerable variations in torque, and require only a small power from the middle, and the heavier shafts from the end, or if of exceptional length, from both ends. The modern method of driving spinning and preparing rooms is to run the shafts at 485 r.p.m. (softener and card shafts being sometimes run at a lower speed) and couple the motors direct through flexible couplings. An example of such a drive is given in Fig. 17, which shows a modern drive, the motors being placed on masonry piers connected together by a platform, and the motor starters on the ground. Another example of a recent installation is illustrated in Fig. 18, which shows in the foreground the larger motors for the preparing and spinning rooms direct coupled to their respective shafts,

and in the background smaller motors driving the weaving shed shafts through chains.

Weaving shed shafts should not, under any circumstances, be increased in speed beyond that speed which gives approximately a one to one pulley ratio. An attempt was made a short time ago, to increase the speeds of weaving shed shafts to 368 r.p.m., with results that might have been foretold, when it is remembered that a jute loom takes over twice normal torque at the start, is frequently starting and stopping, and has besides a very irregular torque curve, as was seen from Fig. 6. In this case the motors had to be removed, and the shafting reduced to the normal speed.

If a machine runs intermittently or requires complicated shafting to drive it

FIG. 16.—Group Electric Drive with Rope Transmission (Calcutta).

FIG. 17.—Group Electric Drive with Direct Coupled Motors (Calcutta).

FIG. 18.—Motor Alleyway of a Modern Jute Mill (Calcutta).

it is probable that it will be desirable to drive it individually. If, too, an exceptionally steady speed is required, as is the case, for instance, with spinning frames and automatic looms, individual drive will almost certainly prove most suitable. It is further, eminently desirable that all irregularly running machines, that is, machines which "start" or "stop" frequently, or machines, on the other hand, that have an irregular torque, should not be allowed to interfere with the steady running of other machines on the same line shafting. These should, therefore, be driven by individual motors.

Reference to Fig. 13 will show the serious effect on the power load of a line shaft

in a jute mill of the irregular torque of a jute mangle driven from the shaft, and no further proof should be needed of the importance of removing such irregular running machines from line shafting which has to drive machines that need a steady speed. A similar case would be that of spinning mules in a cotton mill. Here it is clearly desirable that the mules should be separately driven, and not allowed to interfere with the smooth running of other machines. *Softeners* should be individually driven. They furnish an irregular load, and a long line of shafting, idle for the greater part of its length, is required to drive them on the group system. Spinning frames lend themselves admirably

to individual drive. An example of a drive suitable for roving, slubbing and spinning frames is given in Fig. 4, the illustration being from an installation put down by the author in an asbestos factory. This, it may be added, is the only illustration given in the paper, which is not taken from a jute factory. Direct coupled motors can be used for spinning frames where the speed of the tin drums can be increased to permit of a motor of standard speed being used. In this case, however, the motor must be of special design, or the drive so arranged as not to give too abrupt a start, which is liable to cause yarn breakage in frames of the "flyer" type.

For *Looms* the individual electric drive is ideal, and its application for this purpose has been exceptionally rapid. It will be possible to deal with only a few of the leading features of this drive, an example of which, from a modern Indian mill, is given in Fig. 8. Fully enclosed three-phase motors capable of giving a high starting torque, with a remarkably high efficiency over a wide range of load and arranged to be suitable for belt or single reduction gear drive are employed. In the case of the belt drive, springs are introduced into the motor mounting so as to give the flexibility needed to deal with shafts which are sometimes out of truth. When gear drive is desirable, as in the case of low speeds, and for delicate materials, a slipping coupling is introduced, which is so adjusted as not to slip at start, but only on the abnormal overload produced by what is known to the textile manufacturer as a "knock-off."

The most remarkable feature of individual loom drive is the increase in production that results from its use. Through the courtesy of the Agents of a large Indian mill,* where he installed this drive, the author has received permission to publish comparative tests taken over a period of twelve months between some hundreds of looms running on "Hessians" and "Sackings," and driven mechanically by a modern reciprocating engine and a similar number of looms driven by individual electric motors. The individually driven Hessian looms showed an increase in production of 13 per cent., and the Sacking looms an increase of 8 per cent. over their mechanically driven neighbours. In the Mill Engineer's report, it is stated that the

coal consumption with the steam drive is very considerably in excess of that with the electrical drive, that there is a very considerable saving in regard to labour and oil, and what is of considerable importance, in mechanical upkeep on the looms, and he concludes: "It is possible to build a mill and drive it electrically, paying for it by the amount saved in running cost together with the increased production, in a period of from three to four years, or even less, if an exceptionally prosperous season and market favour one."

Individual electric drive should be applied to *Dressing Machines* (Fig. 8), and to *Damping Machines* (Fig. 9), which run intermittently, to *Calenders* (Fig. 10), *Mangles* (Fig. 12) and *Hydraulic Pumps* (Fig. 14), which provide an irregular load. *Cropping Machines*, *Measuring Machines* and *Calenderers*, and, indeed, all machines which "do not run continuously, should also be put on single motor drive.

The individual electric driving of calenders with chain transmission as illustrated has proved very successful in practice, and also a similar motor arrangement with gear or worm drive. A small motor, visible in the foreground, is provided for driving the auxiliary shaft.

For driving mangles laminated belting has proved satisfactory, the motor being of the slip-ring type, and fitted with a large flywheel to enable the peaks of the load curve (Fig. 11) to be negotiated.

(To be concluded.)

OBITUARY.

DR. ALEXANDER GRAHAM BELL.

Dr. Alexander Graham Bell, the inventor of the telephone, whose death took place on the 2nd of August, at his summer residence on Cape Breton Island, will certainly be remembered amongst the world's great inventors—men whose original work has profoundly affected the daily life of civilised mankind.

A Scotchman, born in Edinburgh in 1847, Graham Bell came of a family associated with the teaching of elocution, his grandfather in London, his uncle in Dublin and his father, Andrew Melville Bell, in Edinburgh, being all professional elocutionists.

* Wellington Jute Mills, Calcutta.

Graham Bell was educated at the High School and at the University of Edinburgh, and in 1873 migrated with his father to Canada. It was there that he conceived his great idea of the speaking telephone, but the first instruments were not constructed till he went to live at Boston in the United States, where they were completed in the year 1875. Exhibited at the Philadelphia Centennial Exhibition in 1876, Bell's telephone immediately attracted world-wide attention. It was there that it was seen by Sir William Thomson, afterwards Lord Kelvin, who brought it to the notice of the British Association in Glasgow in the autumn of the same year.

As originally constructed, Bell employed the same or similar instruments both for transmitting and receiving. This gave very distinct, though somewhat weak, articulation, with the result that particularly over long lines, speech often became too faint to be practicable. It remained for Edison, Hughes and Hunnings to invent the more powerful microphone transmitters that are now used, but Bell's instrument, practically in one of the forms in which he left it, is still universally employed as a receiver. Seeing of how few parts it consists, and the wonderful results that it gives, it has been well described as an instrument of sublime simplicity.

It is unnecessary to enlarge upon the enormous developments in telephonic communications that have taken place all over the world since the date of Bell's invention, during the last forty years, but apart from its great commercial and domestic utility, it should not be lost sight of that Bell's telephone is a scientific instrument of surpassing delicacy for the detection of very minute electric currents. In this connexion, it has been put to many uses, and none more so than in wireless telegraphy, which could scarcely have arrived at its present advanced stage of development without it. Further, of course, without Bell's invention, wireless telephony could scarcely have existed at all. Out of the telephone both Graham Bell himself, and also his father-in-law, G. G. Hubbard, who assisted in the financing of the invention, made princely fortunes.

Another invention of Bell's was the photophone, in which articulate speech is transmitted along a beam of light. In perfecting this instrument, he was assisted by Summer Tainter. Though of considerable

scientific interest, and used to some extent in the great war, this invention has never proved of commercial utility.

Of more practical importance was Bell's valuable contribution to the phonograph. In this instrument, as originally invented by Edison, in 1877, sounds and speech were recorded by indentations on tinfoil. This method gave very imperfect reproduction of the original sounds, until Graham Bell, assisted by his relative, Chichester Bell, and again by Summer Tainter, introduced, in 1885, a method of recording by means of a cutting style operating on wax. This method now forms the basis on which all modern gramophone and phonograph records are made. It should also be mentioned that Graham Bell took an early interest in aviation, being the chairman of an association of experimenters which, under the name of the Aerial Experiment Association, did much useful pioneer work as long ago as 1908.

Bell three times honoured the Royal Society of Arts by personally lecturing to its members. His first discourse, which was on his telephone, was given in November, 1877, when the crowd to hear him was so great that large numbers of members were unable to obtain admission to the lecture hall. The Council thereupon requested Bell to repeat his lecture another day, which he did.

Bell's third lecture to the Society was on the photophone, and took place in December, 1880. Prior to this, he had been awarded the Society's silver medal for his previous paper on the telephone, and also in 1878, he was elected an honorary life member of the Society in consideration of his invention of the telephone. Further, in 1902, the Society's Albert Medal was conferred upon him. Amongst other honours, he also received the Hughes Medal of the Royal Society in 1913, and during a visit paid to this country in 1920, he had conferred upon him the freedom of his native city in Edinburgh.

Bell had an imposing appearance, but a very delightful and modest personality. Some years ago he told the present writer that he did not pretend to be an electrician; indeed, some of his friends informed him that he could not be one, as otherwise he would have known beforehand that his telephone would never work.

PROCEEDINGS OF THE SOCIETY.

TWENTIETH ORDINARY MEETING.

WEDNESDAY, 26TH APRIL, 1922.

SIR JOHN F. C. SNELL, M.Inst.C.E.,
Chairman of the Electricity Commissioners,
in the chair.

The paper read was:—

THE USE AND ADVANTAGES OF ELECTRIC POWER IN THE FACTORY, AS ILLUSTRATED BY ITS APPLICATION TO THE JUTE INDUSTRY.

By J. F. CROWLEY, D.Sc., B.A., M.I.E.E.

(Concluded from page 689.)

THE ADVANTAGES OF ELECTRIC DRIVING.

Much has been written in favour of electric driving in the factory and the workshop, and it would not serve a useful purpose to-night to go over old ground. There is, however, one outstanding feature of the drive which will probably, from what has been said, stand out in bold relief in most minds, and that is, the increase in the productivity of the driven machines that the proper application of electricity can give. The amount of this increase is dependent naturally on how far, in arranging the layout, advantage has been taken of the drive. It varies with the class of material dealt with, and while it is obtainable with group, as well as with individual electric drive, it is in connexion with the latter that it most definitely manifests itself. So far has this been recognised that, to quote a recent writer, Mr. W. Sutcliffe, "one of the largest textile combinations in this country decided, some years ago, after considerable experience, to adopt individual driving for all machines other than those connected with the preparatory processes, the chief factor influencing this decision being the superiority of the drive for spinning and

finishing as shown by the improved evenness and quality of the finished goods. This firm has now upwards of 11,000 induction motors operating in their various mills, the great majority of these being under 10 H.P. of the squirrel cage type and driving individual machines."

When it is added that the author has, during the past ten years, and notwithstanding the war, installed over 12,000 individual drive motors, it will be clear that the merits of this drive have come to be recognised by the most conservative manufacturers.

The great advantage of any increase in production secured from the drive lies in the fact that it is obtained without any increase in building space, productive machinery, rent, rates or taxes, and its effect on profits is consequently more striking. The author was able to show,* a few years ago, that an increase of 10 per cent. in the production of a Lancashire weaving shed which was obtained through individual electric driving was equivalent to an increase in profits of over 30 per cent., and while it has not been possible to obtain the detailed information necessary for a similar general investigation in the case of the jute industry, sufficient data has been obtained to show that for Indian jute mills in particular the effect on profits of such an increase is more nearly 50 per cent. than 30 per cent.

This is a striking result, and, in the author's view, furnishes a solution, if not indeed the only solution, of the problem that is facing the manufacturer who has put down a new mill, during or since the war, and finds himself forced to carry a very greatly increased capital expenditure and at the same time to compete with mills erected in happier circumstances, and the greater part of whose capital has, in many cases, been written off.

If electricity furnishes the solution of this serious war problem, and the author believes that it does, it will, as the Chairman pointed out in his opening remarks, have done for this generation what the steam engine of James Watt did for the generation that lived through the depression following the Napoleonic wars—an achievement that it must be conceded would be no mean contribution to the solution of the Peace Problems of the World. The author desires to acknowledge his indebtedness to the Chairman (Mr. McKenzie) and Committee of the Indian Jute Mills Association

for very valuable assistance; to the Chairman and Secretary of the Association of Jute Manufacturers and Spinners, Dundee; to the Secretary of the Chamber of Commerce, Dundee; to Mr. C. R. Orr, Edinburgh, who kindly read through the proofs, and whose criticism was very helpful; to Mr. L. T. Miller, Dundee; and, finally, to the English Electric Company for permission to use the various photographs of plant.

DISCUSSION.

THE CHAIRMAN (Sir John Snell) said that it was usual for the Chairman at these meetings to open the discussion, but on this occasion he was bound to say that he felt singularly incapable of beginning a useful discussion on account of the special knowledge which was required in connexion with the application of electricity to textile industries. Some years ago he had a slight connexion with Dundee, at the time when that city was beginning to build its new power station, and the application of electricity to the textile mills in that town had to be considered. But it would be futile for him to criticise any of the special technical points in the paper. There were one or two general matters on which he might make comment. Dr. Crowley had remarked that there was a tendency to give up the individual generating plants and to take energy from a public source. He was glad to say that that policy was not confined only to the jute industry. He believed that the mills at Dundee were beginning to take their supply from the public system, but certainly in the Lancashire cotton area and also in the worsted area of Bradford and the West Riding there was an increasing tendency for the textile mills to utilise public sources. A few years ago there was a very heated controversy as to the relative advantages of the individual mill engine drive with long lines of shafting and the electrical drive, but the lantern-slides that evening had made it very clear, he thought, even to those who were not experts in the matter, that the absence of so much counter shafting and belting must have an important effect on the employee, not only from the point of view of lessened danger, but from that of lessened noise and distraction. He imagined also that it must have an effect from the point of view of the light available in the building, quite apart from the most important point of all—namely, increased production due to steadier drive. If one were asked to weigh up the evidence given by the author, though perhaps this was *ex parte*, one would say that he had made out a very clear case for electrical driving, and particularly by individual motors. Of course, he took it that an expert who had to deal with the application to textile mills was confronted with two problems: (1) the matter as it related to the creation of new mills, which

*"The Individual Electric Drive in Weaving Sheds."—*Journal of the Association of Managers of Textile Works*, March, 1912.

was perhaps the easier problem, because there he had a clear field, and anybody who looked at the pictures just shown of the galleries outside the actual factories, as it were, must have been struck with their neatness and easy accessibility, the better grouping of machines, and better design of factory as a whole, which was possible when the problem had to be tackled *de novo*. To those who were textile experts it might be that what he was saying was utter nonsense, but, speaking as a layman, that was the impression made upon him. But the second problem was the more difficult, the application of electricity to an existing mill. There Dr. Crowley had shown that instead of driving from perhaps the end of a shaft through long lines of cross shaft, by grouping the important motors in the middle of the system, not only was the total variation reduced by something like one quarter, but with the electrical drive the starting of machines was more prompt, so that there was an even greater gain. There could be no doubt—and it was a very important thing to a person in his position to have assurance on the point—that there was in these great industries, whether flax, or cotton, or jute, a recognition on the part of the manufacturers that electricity was bound to play a very important part, enabling them to cope more readily with increasing competition, not only from foreign countries, but even from our own Dominions overseas. In this country the tendency in the north and north-west of England was to rely more and more upon the public sources of supply. As he had indicated at the very beginning of his remarks, this country, with the increasing competition which it had to face from abroad, especially from those industrial countries that were blessed with many natural resources like water power, had got to put its last ounce as it were into increased production and reduced costs if it was going to maintain itself against competition effectively. It was of the utmost importance that there should be the completest accord between the great electricity supply undertakers, the electricity plant manufacturers, and the industrial manufacturers, so that instead of adding to the difficulties of the industrial manufacturer by causing him to put in his own generating plant, he might be able to save that capital money and get his supply from public sources with perhaps a greater degree of safety to his supply than would be the case were he dependent upon his own single plant. A liaison between the electricity supply undertaker and plant manufacturer and the industrial manufacturer ought to be an important factor in maintaining the satisfactory competition of this country with other countries and conserving, as he sincerely hoped would be the case, its industrial supremacy. The only other point upon which he would like to touch was this: it had been noticed that in India there was a very great tendency to introduce American electrical machinery. As was well known

to many who were present, the standard frequency of that country was 60 cycles, whereas our standard frequency in this country was 50. It was important for us to remember that the Imperial Government of India had permitted large installations of 60-frequency plant to be introduced into that empire. This made it very difficult if not impossible to compete, or even to supply the separate parts for such machines. He devoutly wished—and he spoke from some official standing—that for the sake of the Empire as a whole and for the sake of our manufacturers at home there should be some understanding between the Governments of our great Commonwealths overseas and the Imperial Government, whereby at any rate the British standards should obtain throughout the whole of the British Empire.

MR. W. H. PATCHELL, M Inst C.E., said that the author had shown them very plainly that electricity was not a prime mover. He had also shown them another instance of the excellent means of transmission which it is; they did not yet know a better. The conversion of an old mill was a different proposition from the laying out of a new mill. Dr. Crowley had spoken of mills with a shaft 700 feet long. The individual drive was absolutely the ideal theoretically, and the nearer one approached to the individual drive the more was friction cut out and production increased. But the pendulum must not be allowed to swing too far. Messrs. Coats at one time let in Ferranti, who tried an individual drive on each spindle. Electricity in the ordinary way would not supply steam, and that was a consideration, for exhaust steam utilisation represented a great saving in coal. What was the cost of driving in a textile mill? In England they were badly off for anything like details. They had to go abroad for useful data. The last data he could find related to 1914, and showed the cost of driving power and fuel in the textile industry to be 1.3 per cent. of the cost of the finished product. The other costs were:—

Raw material	57	per cent.
Wages	19.7	per cent.
Other costs and profit	22	per cent.

If, therefore, it was a matter of only 1.3 per cent. with which to play, the cost of the finished product was not going to be materially affected by varying the cost of power. Another point which came out in these figures was the average horse-power of motors, which had fallen very considerably, and showed the tendency towards the individual drive. He could say nothing about Calcutta, of which the author had spoken, but thirty years ago he assisted at setting up the first station in Dundee. It was a direct current station, 400 volts, three-wire. Like most other plants which were started direct current, it had now become alternating, and it was also interesting to note that the first jute mill which was started in Dundee—the author gave them approximately

the date, and it was many years before a mill was started in Calcutta—was on a site now occupied by a technical school, which did its best to teach young Dundee how to spin jute. The speaker added that he would like to say something about statistics. He believed what had most affected the price of current in this country was the publication of the costs. The Board of Trade got out schedules, which they did not use, but pigeonholed, whereupon one of our enterprising journals, the *Electrical Times*, performed a service which this country could never forget by analysing and publishing these statistics. He believed that this, more than anything else put those of them who were making juice into healthy competition with each other and brought down prices. Was it not possible now to get something useful in the way of statistics? With the Geddes axe hanging over their heads it might not be possible for the department over which the Chairman presided to set a large staff on to working up statistics, but he thought it might be possible when opportunity arose to get the undertakers to deliver to the department such statistics, not only on the financial but on the technical side, as would show what they were doing and would help them to do better. It was only in that way, by all putting their cards on the table, that they could make progress, and he believed that public utility companies ought to show to the public what they were doing so that the public might have the advantage. He hoped that one outcome of the paper would be that the statistics collected by the Chairman's department might be made more useful and more fully used, even though the analysis of them was left to private enterprise.

THE CHAIRMAN assured Mr. Patchell that the question of statistics was already in hand, and questionnaire forms had already been sent to the undertakers.

MR. THOMAS WOODHOUSE (Head of the Weaving and Designing Department of the Dundee Technical College) said that he had been in favour of individual driving for a number of years, but he could instance some little difficulties in connexion with that system for certain particular machines. Ten or eleven years ago he had nearly all the machines under his control individually driven. The advantage of the individual drive, apart from uniformity and increased production, was that a loom could be started even with the crank on the front centre. A difficulty often arose over the starting of some machines. There were machines which must start quickly, but others must start slowly, and the greatest difficulties from irregularity came from the machines themselves. He had been able to obtain a few picks per minute increase in individually driven looms, by means of a laminated belt, while he had first-hand information that an increase of 10 to 15 per cent. over steam-driven looms had

obtained by individual motor drive. The gain, in his opinion, was not due in all cases to any large extent to increased speed, but to more uniform movement, fewer stoppages, and minimum breakages.

MR. C. G. RENOLD said that he had been very much impressed by the point Dr. Crowley had made of the possibility of reducing the cyclical variation of shafting by the introduction of motors up and down the place and driving at a number of points instead of from one centre. This dispersion of the points of driving is very much facilitated by the use of chains. If one was going to hitch a motor on to the middle of a line shaft, one had the choice of doing it by gears, by belts, or by chains. There was nothing more difficult than to get gears sufficiently accurately aligned and this did not apply to chains. If belts were used the possible locations of the motor were very much restricted by the requirements of a satisfactory belt drive. If chains were used the motors could be placed almost anywhere where space could be found and still a satisfactory drive obtained. The chain drive was, of course, equally positive with gears. It would be interesting to know whether in connexion with the cyclical variation, the author had any figures furnishing a direct comparison between chains and belts. Some interesting experiments were made years ago in his own factory in the driving of automatic lathes. The test had been undertaken to measure the following features: Total production, quality of work, i.e., finish of machined surfaces, life of tools, power absorbed, wear and tear of machines. The tests were made with the machines working at their maximum capacity. It was found that the speed was limited by considerations of "finish," the belt driven machine producing much rougher work than the chain driven. When both machines were run at the same speed (the maximum possible consistent with "finish" on the belt driven machine) the total output from the chain driven machine over a test of 138 hours was 23% greater than that from the other. This was due to a fewer number of stoppages for tool sharpening. The life of the various tools was from 4 to 5 times greater on the chain driven machine; the power absorbed was 20% less, due to the heavier loads on the bearings produced by initial belt tension, and the wear and tear of the machine bearings was noticeably less in the case of the chain driven machine for the same reason. The results as regards "finish and life of tools," with its consequent effect on total production could only be attributed to "chatter" set up by irregular slipping of the belt, or by its stretching and contracting in a kind of concertina fashion as the load changed, due to the various cuts. The chain, by giving a smooth regular turning, enabled the machine to do work beyond its normal capacity, to produce work of good finish and to get a greater life out of the tools.

The net result was a considerable increase in production. It would be interesting to know whether similar results had been noticed by the author. He was also interested to see some of the slides showing large mangles. He was not very familiar with the jute industry, but in the cotton industry it had been found a great advantage to drive these mangles and calenders by chains. In cotton work particularly, where a fine finish was wanted, driving by chain had a great advantage. One could eliminate, in this way, wave-marks on the fabric which were produced by the gears, and one could avoid quite a number of breakages—tearing of material—which one got with the gear drive. The advantage with the chain drive was attributed by the people who used it to a certain flexibility—the chain drive was so to speak “kinder to the fabric” than the gear drive. Possibly with jute the same condition did not hold good, due to the finishes not being so high or the fabric so delicate.

MR. W. SUTCLIFFE said that Mr. Patchell had referred to the individual drive on each spindle which was designed by Mr. Ferranti for a large textile concern in Scotland, but it should be remembered that in this case the motors employed were of the pneumatic variety and not the electrical. Experimental jute frames, however, had been built with a small motor applied to each spindle, but obviously this was carrying individual driving a little too far, and needless to state the proposal never got beyond the experimental stage. There was no doubt, however, that every machine in a jute factory could be driven individually and the only two machines which presented any difficulty were the card and the mangle. In the former case a good individual drive could be obtained by employing a centrifugally operated clutch, which allowed the motor to attain nearly full speed before coming into operation; as regards the latter, Dr. Crowley had that evening, described to them a method of applying the individual drive, and they would be interested to learn that the drive in question had been in successful operation for the last eight years. Dr. Crowley had referred to the practice of the Calcutta Supply Authorities in recommending their consumers to adopt high tension motors with stators wound for 3,000 or 6,000 volts, but it would be seen that this imposed a very great difficulty on the designer of the electrical layout, since it precluded the adoption of small motors owing to the impossibility of their being wound for the high voltage. In fact, it simply meant that such a recommendation put individual driving out of court altogether and left the consumer with little choice in the matter. He agreed entirely with Dr. Crowley that such a recommendation could not be too strongly condemned since it was an obstacle to progress. On the question of power factor, it had been stated that

central station engineers would make an extra charge if the power factor of an installation dropped below a certain figure, and in his opinion no serious objection could be taken to this since it was well known that a low power factor had the effect of limiting the capacity of the generating plant and main system; on the other hand, however, he thought that an inducement should be given to users of electricity to obtain as high a power factor as possible, and in this connexion would mention that in Dundee and Glasgow most generous rebates were given to consumers whose power factors reached .9. The curves shown by Dr. Crowley were most interesting, particularly those showing the cyclic irregularity at various points in the mechanical transmission of a weaving shed, and they confirmed his own ideas on the matter. It was well known that in some of the Dundee factories some of the larger looms could not be satisfactorily driven at the extreme ends of the shafts owing to the cyclic irregularities of the intervening shafting. The extent of angular twist in a shaft was perhaps not fully realised, but it might be stated that with shafting over 300ft. long it became considerable. Shafting tables were usually based on a torsional stress of 5000/6000 lbs per sq. inch, and elementary calculation would show that any shaft loaded to that value would have an angular twist of 1 degree for every 20 diameters of shafting; that is to say, a loaded 4in. dia. shaft would have a twist of 1 degree for every 80in length. Taking the case instanced by Dr. Crowley, in which there was a shaft 700ft long, it would be seen that the angular twist at the extremity, assuming uniform distribution of loading throughout its length, would exceed 100 degrees. This would not be a very serious matter if the load were absolutely steady, but as a matter of fact such a condition never occurred and therefore the twist would be a variable quantity between the limits of zero and maximum, depending on the instantaneous load carried. In the practical arrangement of shafting it was, of course, usual to reduce the diameter at intervals along the length on account of the diminishing load and the effect of this would be to keep the torsional stress loading fairly constant; thus the figure for angular twist previously referred to, i.e., 1 degree of twist for every 20 diameters of shaft, would still hold good, but the calculations for a shaft so graded or tapered would show that the twist at the extremity, say of the 700ft. shaft, would be considerably worse than the figure he had previously given. He thought this was a point that perhaps in the past had not received the consideration that its importance demanded.

COLONEL H. SPARKS referred to the jute industry in the United States, particularly one large American concern. It was very difficult to say exactly what was the saving by the application of electric power. They started twelve

years ago in New York, and went through much of the experience which had been brought to their notice that evening. In the case of one mill the consumption of units was now about eleven million per annum. This large concern did not stop there, but went on with the electrification of their mills in other cities. These were cases of conversion. Next came the industry starting *de novo*. A mill was put down in Calcutta and worked on the same lines. That was one large American concern, and what it had done it had done successfully and was well worthy of consideration. One advantage of getting power supply from outside was that the manufacturer might then apply himself wholly to his particular industry—for example, jute. With regard to the individual drive, he believed that one of the biggest firms in the silk industry drove each spindle with an individual motor.

MR. PETER KILGOUR said that there was one point which Dr. Crowley had omitted, and which was of extreme importance—namely, the reduction in waste which took place under electric power. If one sold waste one got coppers for it, and if one sold cloth one got pounds! The speaker mentioned an instance in which some spindles in a mill were driven direct with friction, Leslie's patent, instead of by means of a band. About fifteen years ago in a factory with which he was concerned, a few machines were put in to be chain-driven instead of belt-driven. The chains after running four or five years showed no signs of wear, and the drive was so perfect that from 5 to 7 per cent. of wastage was eliminated. He mentioned also that in Dundee they had one shaft which, like the one mentioned by the author, was over 700 feet long.

DR. CROWLEY, in replying to the discussion, said that there was no time to reply in detail, and he could only refer to one or two of the points which seemed to traverse the paper more directly. With regard to the remarks of Colonel Sparks as to the development in textile work in America, of course America was definitely developing in the direction of individual driving, and was far more advanced in that connexion than Britain. It was quite unusual to find automatic looms there driven mechanically in the way they were driven here now. With regard to test results, definite test results were available in the textile factories of this country taken on machines driven in the old way and on the latest electrical system. If there was one thing more than another that the manager of a factory did know it was his output. He would append to the paper the results in one case in Calcutta. With regard to the spindle-drive question, Mr. Patchell had criticised a particular case, but this, as a subsequent speaker had said, was a case of a pneumatic drive. In the artificial silk industry the spindles, which were particularly heavy, were successfully driven

individually, but the spindles in this case were heavy enough to justify it, whereas the smaller cotton spindles were not. In the old spinning frame of the normal standard type, it was not easy to realise the power that was lost, but by simply inserting in a frame, that had done duty for many years, an auxiliary tin drum, the number of spindles per horse power, which had been 11.2 before the drum was inserted, became 16 after the insertion. People had not realised the power that was lost in that particular case. In reply to Mr. Woodhouse, the difficulties presented by starting torques and the cyclic irregularity in torque of the machines had been completely got over in most cases. There were electrical and mechanical means of overcoming all these difficulties. The cyclic irregularity in torque of particular machines must be recognised. Such irregularity was particular to the machine, and the individual motor yielded to the varying torque and did not upset production, whereas what really did upset the machine were the oscillations of the driving shaft produced by other machines and imposed upon it at the wrong moment.

MR. PATCHELL, who had taken the chair, as Sir John Snell had had to leave the meeting, proposed a vote of thanks to Dr. Crowley, which was heartily accorded.

— — — — —
- MR B. J. M. LANE, B.Sc., A.M.I.E.E., writes:—

Dr. Crowley, who has done a large amount of pioneer work in connexion with the application of electricity to mills and factories, has been able to speak with authority on this interesting subject, and has incidentally covered a large range of work.

The author has referred to restrictions made by certain supply companies with regard to the power factor. This is a much-discussed point, but it is generally recognised that there should be a differentiation between consumers working on a low power factor and those working on a high power factor. Where such technical regulations exist, they tend to have their effect upon the motor mill equipment, as for instance, to the detriment of flexibility of the drives. Means may be used to comply with this restriction without interference with the best arrangement of the mill drives. I refer particularly to the means already mentioned by the author, viz., to the use of the asynchronous-synchronous motor or the oscillating phase advancer set. One machine, or possibly two or three machines of this type, depending upon the amount of power factor correction required, may be used in the place of the ordinary induction motor for the drives where the largest amount of power is being consumed. Such machines are by no means new and they already possess a fair field of application. Their cost is not very much above that of an ordinary

induction motor of the same size and speed, so that this point forms no stumbling block, and the extra switchgear involved is small.

On comparing the relative costs of asynchronous-synchronous motors with standard induction motors I find that the cost of asynchronous-synchronous motors up to 200/300 H.P., and down to approximately 428 R.P.M. is 25 to 30 per cent. more, whilst on the higher outputs this figure drops to approximately 15 per cent. On low speeds, say 214 R.P.M., the prices are approximately the same.

The cost of an oscillating phase advancer set lies approximately midway between that of the induction motor and that of the asynchronous-synchronous motor, that is, a 200/300 H.P. phase advancer set of 428 R.P.M. or above would be approximately 15 to 20 per cent. higher than the induction motor price. Below about 428 R.P.M. the price is practically the same as that of the induction motor.

Salient-pole type synchronous motors figure at approximately the same price as the asynchronous-synchronous machines.

One great advantage of the application of the asynchronous-synchronous motor or the oscillating phase advancer set lies in the fact that power factor correction takes place at the seat of the trouble, so that the idle currents in the transmission lines are avoided. This is not the case where special provision is made at the generating station.

The systems of electrical driving in factories and workshops, fall under the two headings of group and individual drive, but one generally finds that a combination of both systems can be employed to the best advantage, the group system being most applicable where the machinery is running continuously for long periods on approximately full-load, and where the process does not call for special features, such as an absolutely uniform and steady speed.

In textile work, group drive applies therefore, particularly to the preparation machinery, whilst the weaving sheds may advantageously be equipped with individual drive, which, although initially the more expensive form of drive, carries with it the great advantage of increased production. This is a point which has been illustrated in a most interesting and convincing manner by Dr. Crowley, whose records taken from Indian textile mills on the variation of the line shaft speeds are, I think, almost unique.

Various suggestions have been made to overcome this line shaft speed variation, as for instance the use of heavier shafts with suitable stopping, and the introduction of flywheels. It is evident, however, from the information that Dr. Crowley has been able to give us that great care should be exercised in the grouping together of the various machines for line shaft drive, for cases have occurred in which it has been found necessary to re-group the machines

before a satisfactory drive could be obtained. I would refer you in this connexion to the article in the *Textile Recorder* which has been already alluded to.

The line shaft speed variation has its greatest effect where materials of a fine quality are being manufactured, and especially in the spinning and weaving departments. Even with coarse material it is certainly desirable that drives of an impulsive nature should be so grouped that the effect of the sudden variations in power is not transmitted to other more sensitive machinery. For this reason, such machinery as jute softeners, mangles, calenders and pumps can advantageously be individually driven.

Jute softeners lend themselves to individual drive. A softener is usually started up light, but it is possible that a stoppage may occur during the process, in which case a re-start would have to be effected against at least full-load torque. It is an advantage to be able to reverse in the event of a choke, although a choke cannot be cleared by simply reversing the motor, and for this reason it is sometimes thought advisable to retain the large driving pulley on the softener for making a number of small movements by hand. The belt also forms a more yielding drive than a chain in the event of a choke, and so is more likely to avoid possible damage to the rollers or bevel wheels.

Jute mangles are difficult to drive owing to the heavy and frequent power fluctuations. The power for a 120-in. mangle will fluctuate from 0 to approximately 80 H.P. every few seconds, and these rapid reversals are very heavy on the clutches, there being two crowned clutches driven in opposite directions, and engaged alternatively by an ordinary cam motion. Jute manufacturers would be only too pleased to get rid of this arrangement, so expensive in its upkeep.

Mangles, of course, may be grouped together, and so driven, but it will be found that in such groups there are moments where the peak loads of perhaps two or three will coincide, which still makes the use of a flywheel and slip resistance desirable.

Jute calenders lend themselves to individual drive, and present no difficulties. A chain drive may very advantageously be employed with the individually-driven calender. Such an arrangement eliminates the open and cross belts driving through friction cones, together with the clumsy lever for engaging or disengaging either cone. There is, moreover, prompt and flexible control.

Various methods of the application of the motor drive where line shafting is employed for the group drives have been given by Dr. Crowley. Where the motor is applied at the middle of the line shaft any speed variation due to fluctuating loads is, of course, reduced to a minimum. It is, however, usually found more

convenient to drive from one end of the shafting as this permits of the placing of the motors in a motor alley-way, clear of the mill proper, the motors and switchgear being fairly free from the mill dust. This is especially the case where the scheme is one for conversion from steam to electrical drive, as there is a rope alleyway usually in existence.

Chain driving has, of recent years, come very much to the front in this class of work, and special attention has been given by leading chain makers to such requirements. Such drives have a very high efficiency, 97-98 per cent., which does not appreciably deteriorate during the life of the chain, which life, with efficient lubrication, may be put at approximately seven years. A fairly large reduction ratio may be used, meaning that the motor itself may be run at an economical speed, and the drive is smooth and positive. Gear cases and efficient lubrication are found to be highly desirable in textile work.

AGRICULTURAL CONDITIONS IN MOROCCO.

Morocco is a Moslem Sultanate on the eastern shore of the Atlantic Ocean. Its boundaries to the north, east, and south are the Mediterranean Sea, Algeria, and the Sahara Desert.

The Sherrefian Empire was founded at the close of the seventh century by Arab invaders, who named it Maghrib-El-Aksa—the "Farthest West." In 1912 the country became a French protectorate, except that the port of Tangier and its immediate hinterland of about 140 square miles is under international control, while a zone extending 207 miles along the Mediterranean Sea from the Atlantic east to the Mulawia River, varying in width from 40 to 65 miles and containing 8,740 square miles, is administered by Spain. The zone of the French protectorate comprises 160,711 square miles, more than one-half of which area (92,664 square miles) is now effectively occupied and under French control.

With a total area of 169,591 square miles, Morocco is somewhat larger than California. The most reliable estimate places its population at 7,023,000; the average density is therefore 41 persons to the square mile. Tangier is estimated to have 63,000 inhabitants, the Spanish Zone 1,075,250, and the French Zone 5,884,750.

In the course of a lengthy report dealing with agricultural conditions in Morocco, from which the following is taken, the United States Vice-Consul at Tangier points out that agriculture is the only important industry in Morocco, where manufacturing in the modern sense may be said not to exist, while the mineral resources of the country are as yet undeveloped. But 10 per cent. of the population of the Sherrefian Empire live in the ports and interior cities, the vast majority inhabiting the rural

districts and directing their energies to food production and cattle raising, from which basic industries are derived all the commodities at present entering into the export trade of the country.

During the war and immediately thereafter Morocco made notable contributions to the food supply of its French protector, shipping to France (from 1915 to 1919, inclusive) a total of 18,460,929 bushels of barley, 3,376,818 bushels of wheat, 3,401,699 bushels of beans, 2,957,247 bushels of corn, 1,146,402 bushels of chick-peas, 1,091,109 bushels of sorghum, 27,504 short tons of eggs, and 75,987 hogs.

In northern Morocco the Rif Mountains describe a regular curve along the Mediterranean from Djebel Moussa (the second Pillar of Hercules), opposite Gibraltar, to Cape Tres Forcas, north of Melilla. The culminating point in this range appears to be Djebel Tiziren (8,125 feet) in the Djebala region. The Rif chain rises abruptly from the sea, but toward the interior of the country its slope is more gentle.

However, the predominant topographical feature of Morocco is the Atlas Range, the snow-clad peaks of which bear their heads 9,000 to 12,000 feet above the sea. The High Atlas chain commences at Cape Ghir on the Atlantic coast, somewhat to the north of Agadir, and stretches away in a north-easterly direction, attaining an altitude of 11,480 feet at Djebel Ogdemt, which, with Djebel Ouichdan (8,200 feet), dominates the valley of the Goundafi. Between the Goundafi and the Tizi-n-Telouet are the culminating peaks of the High Atlas, the Tizi-Tamjurt and the Tizi-Likoumpt. East of Tizi-n-Telouet the High Atlas range is a series of parallel heights, separated by plains and rising gradually up to the principal chain, which attains an elevation of 12,713 feet at the Ari-Aiachi. From the Peak Tizi-n-Telremt (7,156 feet) the High Atlas Range rapidly descends in height towards Algeria.

The Middle Atlas Range is formed of three chains, the most western commencing at the Ari-Haiana (9,840 feet) and ending with the Djebel Tazekka, south of the city of Taza. The highest summit of the central chain is the Djebel Moussa ou Salah (10,558 feet). South of Mequinez and Fez the country of the Beni M'Tir and Beni M'Guild tribes is a plateau rising from 3,280 to 8,200 feet and partly covered by oak and cedar forests.

The Anti (Southern) Atlas Range separates from the High Atlas at Djebel Siroua (11,480 feet) and continues in a south-westerly direction toward the Tazeroualt, between the rivers Sous and Draa, where its altitude is 4,920 feet. East of the Djebel Siroua extends the vast plateau region of the Draa and Tafilalt, 6,560 feet above the sea.

In size, as well as from an agricultural standpoint the French Zone is by far the most important part of Morocco, as within its limits are practically all the arable lands of the country. The fact

that a state of armed insurrection still prevails throughout a large part of the Spanish Zone necessarily reacts unfavourably upon the agricultural development of that part of the Shereefian Empire, the soil possibilities of which cannot be accurately judged until areas now closed are opened to investigation. However, its surface is extremely rugged, and, so far as is known, good farm lands are to be found only in the eastern and western extremities of the zone administered by Spain, particularly to the south and east of Melilla and in the triangle formed by the towns of Arzila, Laraiche, and El-Ksar el-Kebir. It is stated that a large part of this latter area is sown to cereals.

In the French zone the mountainous surface of the Atlas region naturally precludes any possibility of agricultural development, while only the northern part of eastern Morocco is arable. Farming is therefore restricted to the great undulating plains that extend some 325 miles along the Atlantic littoral from Mogador northward to within 50 miles of the Strait of Gibraltar, and inland about 100 miles up to the foothills of the Middle and High Atlas.

Bounded on the west by the Atlantic Ocean, agricultural Morocco may be considered as lying within a line drawn from the port of Mogador inland to Amizmiz (a town 31 miles south-west of Morocco City), then north-east along the foot of the snow-clad Atlas to the city of Taza, and west to rejoin the ocean at Larache, in the Spanish Zone. The territory thus delimited comprises 36,700 square miles. Cultivated farm lands cover approximately a quarter of this area, or 8,500 square miles; while there are 200 square miles of orchards, vineyards, and gardens, 18,150 square miles of pastures, 7,750 square miles of uncleared land, 300 square miles of swamps, and 1,800 square miles of forests, in addition to the nearly 4,000 square miles of wooded lands to be found in the zone of the French Protectorate elsewhere than within the confines of the essentially agricultural zone above defined.

Land bordering the coast and extending 15 to 20 miles into the interior generally consists of a light siliceous soil, rich in humus, slightly acid, in places lacking lime (despite the calcareous sub-strata), and ranging in colour from dark amber to brick red. In places this formation gives way to stretches of sandy soil, more or less stony, but showing surprising fertility under cultivation. Behind this coast belt the soil is a heavy black loam, rich and relatively deep, slightly acid. It is excellent wheat land but rather difficult to work advantageously in seasons of continued rainfall.

Monotonous in aspect, and treeless from Casablanca southward, agricultural Morocco includes the well-watered Gharb and Beni-Ahsen stock-raising regions and the great cereal-producing plains bearing the names (from north to south) of Fez, Mequinez, Rabat,

Chaouia, Doukkala, and Abda. The three last-named regions are especially noted for their fertile black soil, which reaches a depth of about 15 inches in Chaouia and varies between 3 and 4 feet in the Abda and Doukkala districts.

From sea level, this rich coastal belt gradually rises in elevation to an altitude of about 980 feet, where commences the zone suitable principally for stock raising, but including the plain of Morocco City (Marrakesh), which forms the central part of an irrigated district between 18 and 24 miles wide and extending some 125 miles along the foot of the High Atlas to the town of Tadla. Although the soil of this elevated zone is mostly poor and siliceous, by the use of irrigation much fruit and good crops of wheat and barley are obtained in certain parts, where, it is claimed, cotton and sugar cane once thrived. This region ends at an elevation of about 2,230 feet, where commences the forest and mountainous zone.

From the following table it will be apparent that the staple crops in Morocco are barley and wheat; corn, sorghum, oats, canary seed, and millet are next in importance. There are also various regional crops, such as fenugreek, coriander, flaxseed, chick-peas, and beans. Potatoes, string beans, tomatoes, and other vegetables are little grown in Morocco. The crop yields in French Morocco during the period 1917-1919 were:—

Crops.	1917	1918	1919
	<i>Bushels.</i>	<i>Bushels.</i>	<i>Bushels.</i>
Wheat	15,623,608	22,649,517	16,356,747
Barley	31,582,659	35,143,395	26,338,954
Corn and sorghum ...	4,782,505	4,595,171	3,107,531
Beans	1,270,401	1,631,351	1,162,021
Flaxseed	128,032	563,078	608,471
Chick-peas ...	523,193	690,234	486,123
Oats	165,089	266,550	200,544
Millet and canary seed	290,972	227,361	53,442
Peas	15,855	18,274	71,049
Total	54,382,314	65,784,931	48,384,882
	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>
Fenugreek ...	1,714,900	10,168,180	24,336,840
Coriander ...	3,217,720	13,904,660	3,452,680
Total	4,932,620	24,072,840	27,789,520

The wheat mostly grown in Morocco is the hard variety. The average yield obtained by native culture is about 10 bushels per acre. The Moors distinguish several ill-defined varieties of hard wheat. With a view to facilitating local trade in this cereal, a rational classification is being studied by the authorities. The Moroccan wheat generally known as Zraa has a long oblong grain, completely filled; is of a clear yellow colour, and somewhat resembles

the Mahmoudi wheat of Algeria and Tunisia. It is in demand for sowing in rich soil. "Asker" wheat, on the contrary, is more suitable for making hard-wheat flour, and it has a short, small grain, often wrinkled, and is gray in colour. It is cultivated in poorer soils, and even grows in the sand of the seashore.

The cultivation of soft wheat was formerly unknown in Morocco, but, as a result of official encouragement (including the payment of bounties) some 31,485 acres were sown to soft wheat in 1919, compared with 26,125 acres in the previous year. The varieties cultivated are the so-called tuzelle or Oran, and especially the bearded wheat with long grains, imported from Algeria.

The barley raised in Morocco is a 4-row winter cereal resembling in quality that of Algeria; the grain is short and inflated, sharp-edged, and has projecting sides. The average yield is 40 bushels an acre. From 1914 to 1918 a bounty was offered for each bushel of barley produced by European methods and delivered to the authorities.

Oats have been grown in Morocco only since 1912, but their cultivation is slowly increasing—from 3,706 acres in 1915 to 19,900 acres in 1920. The variety grown is light, but of good quality, being of the type produced in Algeria.

Maize thrives well in the rich and deep soil of certain regions of Morocco, especially on irrigated land, although in the coastal belt good yields are obtained without irrigation. Sowing generally takes place in March and the crop is ready for cutting at the end of June. The yellow is the variety principally grown, though early white maize is extensively cultivated in the irrigated districts of Southern Morocco. During the period 1914-1918 maize grown according to modern methods and sold to the authorities received a bounty.

White sorghum is cultivated in Morocco for its grain, from which the natives obtain a flour as much appreciated as that made from wheat. Although the varieties grown are generally white, of medium size, there is also a gray, smaller type. The dry cultivation of Minnesota sorghum was tried at Kenitra in 1917 and a yield of 38 bushels of grain and 129 bushels of green fodder per acre was obtained.

Winter crops in Morocco comprise barley, wheat, oats, beans, flaxseed, fenugreek and canary seed. Barley is sown first, as soon as the sun has dried the earth after the first autumn rains—that is, about the beginning of November in a normal year. Wheat, late barley, and oats are sown in December, and even in January, when the persistence of the rains makes it necessary to wait until then. Cereals rapidly mature and vegetation is much benefited by the sunshine that follows the March rains. The barley harvest commences in May, followed by wheat and oats toward the end of that month,

and prolonged until June. At the same time the harvest of flaxseed, fenugreek, and canary seed takes place. The treading out process commences at once and continues into July and August.

The spring cultures, consisting of maize, sorghum, chick-peas, lentils, etc., are sown at the end of February and during the month of March; they are reaped in August and thrashed in September.

Haymaking takes place at the end of April and during the first part of May.

The principal kinds of soil found in Morocco are as follows (native names):—

Tirs.—A rich black soil of great fertility, especially in rainy years. It is slightly wanting in lime but is strongly impregnated with oxides of iron.

Humri.—Generally red in colour; it is fertile and rich in silicates.

Remel.—Light, sandy soil.

Harroucha.—Contains lime and silicates, but is often stony.

Dahs.—Heavy alluvial soil of a clay nature containing silicates.

These different kinds of soil are found in nearly all regions of Morocco, but, in addition to the fact that their composition renders them more or less useful for cereal production, there are large areas still covered with dwarf palms and jujube and not capable of being cultivated until after clearing.

The native agriculturist in Morocco is not a scientific husbandman. He has, indeed, some idea of the advantages obtained from the rotation of crops and is aware that he should not sow wheat in the same field during several successive years, but his cultivation is generally very superficial, the soil being ploughed only when sowing is actually to be undertaken, while spring and summer soil preparation is completely unknown. The grain is sown broadcast, and usually too thickly. No fertilisers of any kind are used; there is no weeding or hoeing; and, from the time the seed is sown until harvest, no cultivation takes place. Reaping is done with a sickle.

The authorities of the French Protectorate have added to their educational programme the professional agricultural instruction of natives, with a view to training young men who will be capable of directing horticultural work and truck farming and assisting the European colonists in their farming enterprises. Courses in horticulture and viticulture are therefore being given in the Franco-Arab schools of Mazagan, Petitjean, and Temara (near Rabat). Instruction in market gardening and arboriculture is also given in the schools of Ain-Cheggag and Bahlil, near Fez.

Working on shares is a practice common in Moroccan agriculture. Associations between landowners and farm labourers to this effect are the subject of oral or written agreements

witnessed by two adools (notaries). Although each region of Morocco has its particular usages in this respect, agreements to divide the crop on the basis of a fifth or a half are general throughout the country. In the case of a division at fifths, it is customary for the landowner to furnish the land, implements, work animals, and seed, while the labourer supplies only his work and skill. When the agreement provides for a division of the crop by halves the land and half the seed are usually furnished by one party, while the other supplies the work, animals and the remainder of the seed; taxes and costs are borne equally by the two associates. Occasionally, two small landowners form this kind of relationship, each contributing his land, labour, and one-half the seed, the crop and any costs being divided equally.

Although the two forms of association above described are general, there are others, such as those in which the landowner furnishes only the land, the other party supplying the seed, labour, animals, and paying the taxes and costs; or unequal portions of the seed are contributed. The division of the crop then takes place according to previous agreement. If modern power farming ever takes on any considerable extension, in Morocco, new forms of temporary agricultural partnership will undoubtedly come into existence, whereby owners of tractors and other power-driven farm machinery will operate their equipment on behalf of Moorish landowners in exchange for a share of the crop obtained.

During 1920 the Franco-Moorish Government advanced, without interest, more than £20,000 to the 39 native farmer organisations created in the French Zone during the last few years. In forming and subsidising these groups in the various farming communities of the French Zone, the purpose of the authorities was to augment the food production of the country by enabling the Moorish farmers to enlarge and better their agricultural equipment and their herds; to contract collective insurance against hail, fire, and cattle mortality; to form co-operative buying and selling societies; and generally to foster their material welfare by the lending of mutual assistance in cases of sickness, accident, epidemics, locust invasions, and other adversities or calamities. Where poor crops prevent any of the 371,771 members of these groups from retaining sufficient seed grain to sow for the following year, money is loaned from the common fund for the purchase of seed.

These co-operative groups have shown a particular interest in the purchase of modern agricultural equipment, especially ploughs and winnowing machines, which are rented to members in turn, at nominal charges. The advantages obtained from the use of modern farm machinery are, therefore, being more generally appreciated by the native Moorish farmer; and this increasingly wider familiarity

with such equipment may be expected gradually to have an effect upon the quality and yield of field crops in Morocco, as it also opens up new possibilities for the sale of farm implements and machinery.

The difficulties met with by the Moroccan farmer in obtaining loans from banks in the various centres of the country caused the Sultan to issue a decree, dated January 15th, 1919, instituting and organising in the zone of the French Protectorate an agricultural credit system on a basis substantially similar to that of agricultural credit in France. At the base of this system in Morocco is the local *caisse* (office) handling directly with its members the various operations affecting farm credits. These several local offices are affiliated with two central offices, the one at Rabat and the other at Casablanca. These central offices discount the duly endorsed notes of members of the local offices, and may also make advances to the local offices' operating funds. The Franco-Moorish Government has already advanced, without interest, approximately £24,000 to the two central offices referred to, which are the intermediary between the State and the local offices.

Chambers of agriculture have been established at Rabat and Casablanca, with jurisdiction over these two regions of Morocco, where the infiltration of French colonists has assumed its largest proportions.

There are also mixed chambers of commerce, industry, and agriculture at Morocco (City (Marrakesh), Fez, Mazagan, and Saffi. The role of these organisations is to study the means of developing the agricultural riches of the country and to place before the authorities the views of the farming element in matters of rural economy and agricultural technique.

Although the immense majority of the farming class in Morocco are native Moors, many Europeans have entered the country in recent years for the purpose of exploiting its commercial and agricultural resources.

About 400 European colonists (mostly French) are now established in western Morocco. The area in their possession is estimated to be 444,780 acres, of which 370,650 acres belong to Frenchmen. Among these settlers are certain important companies that hold considerable tracts up to 24,700 acres, but in the aggregate the lands they own do not exceed a total of 148,260 acres.

In eastern Morocco a certain number of European settlers have been established since the year 1907, many coming from the region of Oran (Algeria), where they had acquired experience in North African farming. There are now about 90 colonists there, who own a total of more than 94,000 acres, for the most part in farms ranging from 25 to 175 acres. However, several colonists hold some hundreds of acres, especially in the region of Berkane, where there are properties ranging from 750 to 7,500 and

even 10,000 acres. No large agricultural companies are included among the colonists in eastern Morocco.

In 1917 a new impetus to the agricultural development of Morocco along modern lines was given through the inauguration of a movement to encourage French settlers to take up farm lands in the zone of the French Protectorate. This movement comprises three categories of colonisation, namely, small, medium, and large. Small colonisation comprehends truck gardens in the immediate vicinity of urban centres, while medium and large colonisation is a populating movement, having for its object the settlement of a French farming class on lands especially chosen, in proximity to railways. Persons desiring to participate in these colonisation schemes draw lots for the purchase of certain lands or submit sealed bids, the latter method being especially required in the case of farms intended for large colonisation. Payment for these lands is made in instalments. Under the term "large colonisation" are included lands the nature of which is such that they cannot readily be divided into medium-sized farms, or of which the exploitation would require important capital. The reinforcement of the European farming element in Morocco, implied by the continued progress of this colonising movement, foreshadows a correspondingly increased demand for up-to-date farm equipment in a country long closed to all modern influences, agricultural or otherwise.

A decree by the Sultan under date of August 12th, 1913, instituted in the zone of the French Protectorate in Morocco a system of land registry designed to stabilise ownership of rural and urban real property by determining the exact topographic and juridical status of such property and removing all doubt concerning its ownership. This object is effected by means of "immatriculation," or the enrolment upon special registers of all available information concerning a given piece of real property, the determination of its ownership being followed by the issue of a title deed, upon which particulars of all subsequent transactions affecting the said property are inscribed.

The land registry system referred to has not yet been extended to the entire French Zone of Morocco, but is at present confined to the Atlantic coast regions of Rabat, Casablanca, and Doukkala, as well as to the Beni-Snassen region of eastern Morocco and to the town and district of Oudjda on the Algerian border.

From the time this land registry regulation became effective, on June 15th, 1915, until January 1st, 1920, application has been made for the registration of 3,132 properties, covering 434,490 acres. Of this area, 4,775 acres were urban properties and 429,715 acres consisted of rural holdings.

UTILISATION OF THE EAST AFRICAN BAMBOO.

The East African bamboo grows on the high plateaux and mountains of the Colony of Kenya at an altitude of from 7,500 to 11,000 feet. The bamboo forests cover large areas, in some cases many square miles in extent.

The principal bamboo forests are situated on the Kikuyu and Mau Escarpments, the Aberdare Mountains, and the slopes of Mount Kenya and Mount Elgon. The nearest edge of the bamboo forest is about three miles from the railway. The forests are well watered by numerous streams, many of which are of sufficient volume to provide power. Since they are situated at a high altitude, the climatic conditions are well suited for Europeans, but not so well adapted to those Africans whose homes are in the warmer parts of the colony. They, however, soon become acclimatised and do not object to living and working in the cold districts.

According to a report by the United States Consul at Nairobi, it is estimated that the cost of felling and transporting bamboos for a distance of half a mile would be from £5 to £6 an acre. This estimate is based on the cost of manual labour and human portage only. Organisation and supervision would greatly reduce the cost. A fair amount of unskilled labour is at present available.

Although the yield of pulp from the African bamboo is somewhat low compared with that obtained from the Indian, the results of experiments show that a good strong paper, suitable for writing purposes, can be produced. About 1.5 tons of the bamboo were heated with an extra strong solution of caustic soda for 12 hours, and a pulp was obtained which bleached satisfactorily and yielded white paper of good quality. The pulp was converted into a pale-tinted paper, the yield of which (including loading and size) was found to be 41 per cent. of the weight of bamboo treated.

The Government of the Colony and Protectorate of Kenya is inviting offers for the lease of two areas of bamboo forest on the Kikuyu and Mau Escarpments. No tender of less than 2s. a ton will be accepted, the basis of the tender being a royalty payment per ton of air-dry pulp. Licences will be granted to the successful tenderers for periods of 20 years, with options for renewal on terms to be agreed upon. Exclusive right for 20 years will be given the licensee to cut bamboos for the manufacture of paper-pulp over an area to be selected by him in conjunction with the Conservator of Forests within five years of the date of the licence. The areas are estimated to be capable of yielding annually 40,000 tons and 20,000 tons of paper-pulp respectively. Offers must be forwarded to the Conservator of Forests, Nairobi, Kenya Colony, on or before April 1st, 1923.

OBITUARY.

VISCOUNT NORTHCLIFFE, LL.D.

BY LORD MONTAGU OF BEAULIEU, K.C.I.E.,
C.S.I.

No man of our time has had so many varied obituaries written about him as the late Lord Northcliffe. We have seen him pictured in his youthful years as a cyclist and a reporter on one of the cycling papers. It has been related how he started *Answers* with almost immediate financial success. And still later we have heard of him as a great power in the land, almost able to make and re-make Governments, voicing in a curious and persistent way the immediate view of "the common people good enough for me," as Rudyard Kipling says, where lies the residual strength of the British nation. For my part I only intend to write about him as an intimate friend for many years. The chief characteristics that struck me were his power of vision and his personal charm and kindness. Above all was his untiring energy. We have seen it stated that it was this superhuman energy which wore him out, but in reality I do not believe it was anything of the kind. He had at one time a threatening of blindness and afterwards a painful swelled gland in his throat, from both of which maladies he entirely recovered. But the fatal "Streptococcus" germ which found its way into the blood stream was too deadly even for him. When I saw him as recently as last February in India I found him in excellent health and spirits, brimming over with ideas and energy, and then, as ever, confident of the future and of the recovery after the war of the Empire, and of the nation's power to solve the many difficult problems with which India and the great dominions teem.

He had a great regard for science and for the work of the leaders of research, as those conversant with the lectures at the Royal Society of Arts will remember. He often said to me in reference to automobilism, aviation and road-making, subjects in which I was very closely in touch with him, how much further detailed research was needed, and how the hand to mouth methods of the past, especially in regard to road-making, would have to give way to the scientific treatment and construction of our highways.

In his private life no one could have been more charming as a host or as a companion. He was intensely devoted to his old mother, who survives him, to his family and to his

many nieces and nephews. But there was always a tinge of sadness about his position at home, for though he was devoted to his charming wife, he lacked that which he would most have prized in his life—children of his own. Who can say if he had had the softening ties of a family how much more toned down his restless temperament would have been? But as it was the impelling force of great energy and the fund of new ideas ever welling up forbade him to rest. When he was resting from his actual work or his business, as sometimes in the South of France, he was thinking, planning, scheming for the future. It has been well said that you cannot judge an extraordinary man by ordinary standards, and when you are considering the life and character of Lord Northcliffe, you must realise that when he was convinced that a policy was wrong, or that England was in danger owing to the action of this or that individual, he was relentless to the last degree. He would accept no compromise, and proceeded with grim determination to destroy the thing which he hated. This can be seen by remembering what he did about munitions in the war, and in my opinion history will justify what he did by his fierce attack on what seemed to be weakness on the part of the Government towards Germany at one or two critical periods since the war. If he had to entirely cut himself adrift from his friends who stood for or against the policy he approved or disapproved, he did so ruthlessly and often almost bitterly. He was afraid of nobody and nothing—his courage was immense—and England loses a patriot.

Many of us who, like myself, knew him well, will always cherish the remembrance of him as a wonderful companion in many delightful hours on the road at home and abroad, as a brilliant parent of new ideas, and, at any rate in his private life, entirely simple, unspoiled by the possession of money or power, using both according to his lights for the good of mankind and of the Empire.

Viscount Northcliffe joined the Society in 1916, and in the same year was elected a Vice-President and member of the Council, his term of office expiring in 1919. He was re-elected last year. He attended a meeting of the Colonial Section (now the Dominions and Colonies Section) on 11th April, 1916, when a paper on "The Forest Resources of Newfoundland" was read by Sir Daniel Morris, and took

part in the discussion. In 1917, the Council, with the approval of the President, H R H. the Duke of Connaught and Strathearn, awarded the Albert Medal of the Society to Mr Orville Wright in recognition of the value of the contributions of himself and his brother, the late Mr. Wilbur Wright, to the solution of the problem of mechanical flight. The medal was forwarded to Mr. Orville Wright at his home in America—Dayton, Ohio—through the British Ambassador at Washington, and formally presented on 27th October, 1917, the ceremony, at the request of His Excellency, being performed by Lord Northcliffe, then in the United States in connexion with the War Mission, of which he was the head.

NOTES ON BOOKS.

THE METALLURGY OF IRON AND STEEL. Compiled by the Editor of Pitman's Technical Primers (R. E. Neale). London: Sir Isaac Pitman and Sons, Ltd 1922 2s 6d. net.

This small octavo, so thin as to rest unnoticed in the breast pocket of one's coat, arrives with the suggestion that it may prove of some service, especially to the student; but a casual observer may not realise how this can be possible in the present day of large and detailed treatises.

Our monumental text books sometimes tend more towards the minutely instructional aspects than such educational aspects as comparative notes, and other stimulants of a personal expansion of mentality; but the purpose of the book before us is evidently to stimulate the mental or reciprocal interaction between instruction and education. Turning to p 16, we find a schematic section of a modern blast furnace, not drawn with minute structural detail, but highly suggestive to a well-informed student who has read the short paragraphs on the opposite page, in which the five chemical and physical stages are summarised. Our student, if moderately intelligent, will connect these stages with the gradual changes in aspect of the ore, fuel, and flux, as so effectively depicted in the sketch, but the first bright light will step in when the student considers the inner meanings of the temperature curve which is shown alongside the furnace, and when he revises his first impressions by reference to the tabulation of melting points and "industrial temperatures" on pp 96-97.

The student may now realise how much the heat immediately over the hearth is in excess of what may appear necessary for fusion, and he may reasonably conjecture that the function of this excess of heat is to lower the surface tension of metallic particles already in a fused state.

The educational spirit being now active, our student may think of ancient methods of reduction more or less like the Catalan forge method, in which it is practically essential to

use a nearly pure oxide of iron like hematite or magnetite; methods which involve the compression or welding of softened spongy iron, and thus have analogy with Wollaston's method for platinum, also with certain modern methods for tungsten. His mind may now drift back to the commencement of the book and the question raised on p 1 as to the possibility of iron metallurgy having originated by the accidental heating of a piece of iron ore in a prehistoric camp fire. All that we have to suppose is that a piece of magnetite or hematite had been heated in a reducing part of the fire sufficiently long to be thoroughly deoxidised, and that it was suddenly compressed by a shifting of the boulders or stones used for encircling the fire. A careful and ingenious student would perhaps at this stage imitate this sequence by a rather prolonged heating of a scrap of magnetite in a cavity on charcoal (or on a carbon-zirconia compost) before the reducing flame of a blowpipe, then quickly turning out on an anvil and instantly striking. If he happens to have heard of some experiments made about 50 years ago he may now study the metallurgy of the more refractory metals and the alloy steels in a similarly minute fashion; an angular and compact fragment of the oxide, or of intimately associated oxides, being placed at the closed end of a minute "test tube" made of a refractory earth, like zirconia, or the test tube may be made of the oxide of the metal to be reduced; for example of chromic oxide when the enclosure, to be reduced and flattened is also chromic oxide.

Hydrogen, alone or mixed with marsh-gas, is now led into the test tube and the closed end is heated intensely by a warm blast oxyhydrogen blowpipe. Reduction of the enclosed fragment takes place slowly and when judged complete, the test tube is quickly laid on the anvil (the flow of hydrogen being maintained), and instantly struck; the compacted plate of metal being now freed from the wreckage of the tube.

We heartily congratulate Mr. R. E. Neale, the compiler; also Sir Robert Hadfield, who has supplied technical matter, a thoughtful foreword, and has otherwise helped. Their labours present us with that which is so seldom seen, a really valuable small book on a great subject; a book which may be studied with advantage by all engaged in the iron industry from the most experienced ironmaster to the lad who has just entered a village smithy as a blower.

ERRATUM.—In the paper of Major Percy A. MacMahon, R.A., F.R.S., "The Design of Repeating Patterns for Decorative Work," *Journal*, plate IV., Vol. LXX., page 577,

NOTICE.

INDIAN SECTION COMMITTEE.

The Council have appointed Sir George Stapylton Barnes, K.C.B., K.C.S.I., a member of the Indian Section Committee.

PROCEEDINGS OF THE SOCIETY

INDIAN SECTION.

FRIDAY, JUNE 23RD, 1922.

LORD LAMINGTON, G.C.M.G., G.C.I.E.,
Governor of Bombay, 1903-7, in the chair.

The Paper read was :—

IRRIGATION ENTERPRISE IN INDIA.

By F. W. WOODS, C.I.E.,

Late Chief Engineer, Irrigation Department, Punjab

The total area of the British Provinces in India and Burma (*i.e.*, to say, of territory directly administered by British agency) amounts to about 625 million acres, or more than twelve times the gross area of Great Britain.

Of this area little more than one-third, *i.e.*, about 223 million acres, is cultivated and sown annually; whilst little more than one-fifth of the cultivated area is artificially irrigated. The remaining four-fifths of the cultivated area is dependent upon rainfall for its germination and maturity. If in any season, in any locality, the rainfall be deficient, the crops fail and the local population suffers distress; whilst a succession of two or more seasons of drought results in famine.

Of the gross area of 49 million acres, which is irrigated artificially, about two-thirds, or over 30 million acres, are irrigated by means of canals or reservoirs (tanks); the rest being irrigated with water drawn from wells, or by other miscellaneous methods. The canal systems of irrigation

are mostly administered by official agency, and they irrigate annually more than 20 million acres.

2. Of the area irrigated by canals, about half, or about 10 million acres, lies in the Punjab Province; about one-sixth in the Sind portion of the Bombay Presidency; about one-eighth in Madras, and another eighth in the United Provinces; and one-tenth in Behar and Orissa. From an irrigation point of view, the Punjab is the most important Province in India, and it is there that canal-irrigation, and especially perennial irrigation, has exhibited some of its most striking successes—both scientific and financial. It is as one who has controlled the canal administration of the Punjab quite recently, for several years, that I venture to address my present audience.

3. The Punjab Perennial Canals have proved to be most remunerative undertakings. The capital expenditure on them, down to the end of the year 1919-20, amounted to nearly £16,000,000; and the gross revenue derived from their operations amounted, in that year, to nearly £3,300,000; the net revenue to the State, after deduction of working expenses (£800,000), amounting to nearly £2,500,000; or to, say, 16 per cent. per annum on the capital expenditure. The annual interest charges on capital amounted to £488,000; and when we have deducted these charges from the net revenue, we find there is still left to the Government a net profit of 12½ per cent. on the total capital cost of these works.

Figures like these are calculated to fire the imagination of officials, and even of non-officials, in the agriculturally less-prosperous provinces of India; and it seems to be the case, unfortunately, that a contemplation of the successful results of Punjab Irrigation enterprise has led to a degree of excessive optimism, in an adjacent province, which it is my desire to moderate, if possible, by the considerations set forth in the present discourse.

4. The conditions of perennial irrigation enterprise in the Punjab are at present extremely satisfactory; but it is well to bear in mind that they were not always so; for it would be a grievous mistake to suppose that any kind of project of perennial irrigation—prepared without the engineering skill, and the prudence of agricultural and financial forecast, which have been the outcome of slow evolution and experience in the Punjab—is bound to prove successful, without regard to considerations of geodesy, or of hydrography, or of hydraulics, or to any consideration but that of meteorology in a country of scanty rainfall.

5. British enterprise in the development of irrigation in India began with the restoration of the Western Jumna Canal in the year 1820. Previously there had been a canal which had been constructed by the Emperor Firoz Shah, of Delhi, in the middle of the 14th century. It ceased to flow after an existence of about 50 years, but was restored about the middle of the 16th century by the Emperor Akbar, and was improved further, about the middle of the 17th century, by the Emperor Shah Jahan. It fell into ruin or disuse a century later, and was once more restored in 1820 by the British Government, who, however, made no alterations in the alignments, or noteworthy improvements in the design of the canal system.

6. From 1820 onwards, the tracts watered by the canal experienced alternately, from time to time, visitations of famine in years of scanty rainfall, and of epidemic malaria in "wet" years; and it is noteworthy that the abundance of water supply in wet years was as disastrous to agriculture as the shortage thereof in years of drought—quite apart from considerations of human morbidity or mortality.

The restored canal was about 20 years old when it gave rise to terrible epidemics of fever, in the years 1841 and 1843; one result of which was that the Government was obliged to abandon the military cantonments of Karnal (midway down the course of the canal) by reason of the severe mortality amongst its troops there. The depth of water in the canal, which had been four feet in 1820, had increased to five feet in the year 1830, and to seven feet in the year 1835. By the year 1870, it had increased to ten feet.

The Government appointed a Commission to enquire into the causes of the epidemics,

and the Commission (presided over by Major Baker, R.E.) submitted its Report in 1847.

A few years later, in 1856, another severe epidemic of malaria broke out, and we find the Gazetteer recording:—

"In 1856 the people of many of the worst villages abandoned their homes and fled to Jind; and Mr. Sherer, Magistrate of Aligarh, was appointed to inspect the tract. His admirable report was submitted in 1857. He showed that the water level (in the wells) had been raised by the canal from some 60 feet to, in many places, two or three feet only from ground surface; that the fertility of the soil had been very generally diminished, and that the evil had not nearly reached its limits, but must necessarily continue to spread almost indefinitely."

In Mr. Sherer's Report we find:—

"The evil, although developed in different ways, arises from one cause. This cause is the rising of the springs, throughout the tracts affected, to within a very short distance of the surface of the soil."

This was written in the year 1857. Ten years later another epidemic occurred, and General Strachey, Inspector-General of Irrigation in India, wrote:—

"The portion of the canal near Karnal is a disgrace to our administration, and has been for many years past. It creates most pestilential swamps, which must be got rid of unless we are content to perpetuate this abominable nuisance, which has been talked about for the last 25 years, during which no serious attempt has been made to abate it."

Dr. Adam Taylor was appointed to investigate and report on the problem, and made his Report in 1868.

7. The general result of all these discussions of the waterlogging problem was that, in the years 1871 and 1874, 50 years after the restoration of the old *Badshahi* Canal, the Secretary of State for India sanctioned estimates, amounting to over one crore of rupees (£1,000,000 at the then rate of exchange) of the probable cost of re-aligning and re-modelling the Western Jumna Canal. A very extensive system of surface drains was also included in the project, which was carried out to completion by the year 1885.

This expenditure had the effect of reducing the net revenue from 37½ per cent. per

annum on capital cost to $5\frac{1}{2}$ per cent. per annum, and the consent of the Government to this reduction of net profits was an index of its realisation of the gravity of the waterlogging evil.

In the year 1889, also, the Secretary of State for India sanctioned a project for the construction of a new branch of the Canal, extending from above Karnal, to Sirsa, a distance of 140 miles, thereby greatly increasing the area over which the water of the canal was dispersed in irrigation, and reducing the intensity of irrigation per unit of the gross area commanded.

8. The result of these measures has been excellent. The area irrigated annually by the Canal, which averaged about 400,000 acres during the period 1860-1880, and which dwindled to less than 300,000 acres a few years later, now averages about 750,000 acres annually.

This irrigation, however, of 750,000 acres, is dispersed over a gross area of 2,700,000 acres; and the cure of the waterlogging evil in the Western Jumna Canal tracts has synchronised with the reduction of the intensity of irrigation to 28 per cent. of the gross area annually, or to $12\frac{1}{2}$ per cent. of the same in the winter season only.

9. Irrigation canal science was still backward, and the Punjab Canals were still in trouble during the last decade of the 19th century, from various causes. The Sirhind Canal was opened for irrigation in the year 1882, but suffered seriously from deposits of water-borne sand, which accumulated in shoals to such a height that by the year 1893 the question of closing the canal for three months annually during the silting season, was seriously mooted and agreed to. Later on a remedy was found for this shoaling trouble; but not till the year 1901. Meanwhile, the Bari Doab Canal, which had been opened for irrigation in the year, 1859, experienced the waterlogging trouble in its upper reaches; so that in the year 1892, winter, or *rabi*, irrigation from it was discontinued in the District of Curdaspur and part of Amritsar. This trouble is still in being, and is very much in evidence in years of abundant rainfall. Around the city of Amritsar the ground-water lies at a level only about 5 feet below ground surface at ordinary times, and heavy rainfall brings it up to the surface.

In 1887, the (Lower) Chenab Canal was opened for irrigation; but proved a failure by reason of defective design. It

had been designed to draw water perennially from the River Chenab without the help of a regulating weir across the river; but the design was defective for that purpose, and silt-deposits put the canal out of action in the autumn. A weir was built across the river at its head in the year 1892, and the scope of the canal system was vastly increased and brought into effect by the year 1902; since when the history of the canal has been an uninterrupted record of financial success.

10. The year, 1901, 81 years from the inception of British irrigation enterprise in India, marks the date from which the success of all the perennial canals of the Punjab has been fully assured; but the troubles and difficulties through which that enterprise has forced its way ought not to be overlooked in any new schemes that may be devised now or hereafter. These canals have been commercially successful because they were designed with caution, in the light of agricultural and financial considerations, as well as from the point of view of engineering construction; but failure may yet overwhelm any projects, apparently similar at first sight, but essentially different in underlying conditions, if such projects be conceived in a spirit of undue optimism, or in ignorance of the essentials requisite to success in such undertakings. The lessons inculcated by practical experience of irrigation works in the past, especially as regards the risk of waterlogging of the soil, and of silt-trouble in canals, must be intelligently applied to the designs of future irrigation projects, if results as successful in the future, as those of the past, are to be reckoned upon.

11. The great rivers of Northern India, the Ganges and the Indus, and their tributaries, the Jumna, and the five rivers of the Punjab, at the points where they issue from the Himalayan Mountains, on to the alluvial plains, discharge volumes of water varying from 2,000 to 10,000 cubic feet per second in the winter, or low water, season, up to from 30,000 to 450,000 cubic feet per second ordinarily in the summer, or flood season; whilst extraordinary floods of short duration, due to heavy rainfall, occasionally raise the discharges up to from 200,000 to 1,000,000 cubic feet per second.

12. THE SUB-MONTANE ZONE.

At the points where these rivers issue from the Himalayas, the ground surface

of the plains usually slopes away from the hills at the rate of from 10 to 25 feet per mile. Floods of such magnitude, flowing with velocities generated by such steep gradients, have an erosive force far greater than any soil but rock can withstand; hence, in the sub-montane regions, the currents of the rivers erode their channel-soil in the vertical as well as in the horizontal planes; and boulders, in all sizes, from shingle up to stones several feet in diameter, forming the bed of the stream, indicate the erosive power of the currents. Where the rivers issue from the Hills, they are usually from $\frac{1}{4}$ to $\frac{1}{2}$ -mile wide; but as they progress down stream, they widen out, by process of lateral erosion, until, at a distance of 50 or 100 miles, or so, downstream, their valleys, formed by erosion, are anything from one to ten miles wide.

13. THE LOWER EROSIVE ZONE.

At this distance from the Hills, the declivity of each river bed has usually flattened to about $1\frac{1}{2}$ feet per mile, and the boulders and shingle, of the bed-soil further upstream, have given place to coarse-sand and silt formations. In this region, which we may describe as the Lower Erosive Zone, the width of channel or valley eroded by the currents, is far greater than any but the greatest and rarest floods can occupy; so that, ordinarily, even in the summer, or flood, season, the river occupies only a fraction of the width available for it. It flows in one or more main channels, and usually several subsidiary channels; with shoals or reed-grown islands between them.

14. If we draw a line at right angles to the course of the river in the Lower Erosive Zone, and survey the ground levels along that line, we find that although the High Flood Level of the river is high enough to submerge the whole of the riverain, or lowlands, in the valley, it is yet well below the levels of the uplands which set lateral limits to the riverain. This is the distinctive feature of the Lower Erosive Zone, to which I particularly draw attention, as bearing on the problem of irrigation. The lowlands are known as *khadir*, or "hidden," in allusion to their liability to be covered with sheets of water, or with dense vegetation, during the flood season. In the Punjab vernacular they are also known as *Hithar*, or lower. The up-lands are known as *bhangar*, or *utar*, the latter word meaning "upland."

15. THE UPPER DELTAIC ZONE.

The erosive action of the currents in the Lower Erosive Zone tend to flatten the declivity of the river bed; so that, as the river progresses downstream, the erosive action decreases, and a tendency to deposit silt and sand by alluvial action becomes more and more pronounced.

The bed of the river, and the level of the riverain land, gradually rise; and the relative elevation of the uplands diminishes.

In the Punjab this occurs in the region immediately upstream and downstream of the confluences of its rivers with each other and with the Indus; which region we may describe as the Upper Deltaic Zone. In this zone the river tends to occupy, generally, one main channel, which, by alluvial deposit, raises itself gradually higher; so that the riverain land, formed by alluvial deposit from the river's floods, becomes a well-defined ridge, with the river located along the top of the ridge, and the ground surface sloping away downwards on both sides, towards low-lying valleys. Under such conditions, it is obvious that there is a considerable possibility of the river's breaching its banks during some high flood, and deserting its elevated channel on the ridge, for another at a lower level in the lateral valley.

16. THE LOWER DELTAIC ZONE.

Finally, as the river progresses further down stream, it arrives at the true Deltaic formation, in its approach to the sea. At the head of this "delta" it splits up into two or more channels, each of which, forming for itself an ever more and more elevated ridge of alluvial deposit, flows into the sea by a separate "mouth."

17. RIVER GRADIENTS.

We see, then, that if a section were drawn along the bed of a North Indian river, in the vertical plane, the bed line of the river would appear as a curve, of gradually varying curvature, sharper upstream and flattening out downstream, nearly tangential to the vertical at the upstream end, and near tangential to the horizontal at the downstream end.

18. The canals of Lower Egypt, and of Madras, are examples of irrigation canals in the Lower Deltaic Zone, IV. Those of Middle Egypt, Sind and some of the Punjab Inundation Canals may be classed in the Upper Deltaic Zone, III.; whilst the

rest of the Punjab Inundation Canals occur in the Lower Erosive Zone, II. The perennial canals of the Punjab and the United Provinces of India offtake from their parent rivers in the Sub-montane and Lower Erosive Zones I. and II.

19. It is well to bear in mind the difference, in natural conditions, of relative elevation of water and of ground surface in Zones IV., III., and in the riverain lands of Zone II., from those of the uplands in Zone II.

In Zone I. it is hardly necessary to raise the water level of a river, even in the low water season, by means of a barrage or weir across the river, in order to ensure a constant supply of water to offtaking canals. It is in Zone II. chiefly that the necessity of raising the water surface of the river, whether in the high-water season or in the low-water season, in order to irrigate the uplands, above the level of the river's highest floods, has been felt, and has led to the construction of the great river weirs of the Punjab and the United Provinces.

In Zones III. and IV., though weirs or barrages may be built across rivers, in order to raise their low-water levels for purposes of irrigation (as has been done in Madras, Behar, and Egypt), such construction is a luxury rather than a necessity; and it depends upon the particular circumstances of each case whether the country can afford the luxury.

20. PUNJAB IRRIGATION HISTORY SINCE 1901.

It is probable that the high-water mark of irrigation-canal enterprise on the part of British engineers in India was reached by the completion of the Lower Chenab Canal project, in the year 1902, at a cost of about £1,800,000 (270 lakhs of rupees). It was then irrigating annually 1,900,000 acres of land; an area which has since increased to about 2,400,000 acres annually. Its full capacity is nearly 11,000 cubic feet per second (about six times the average discharge of the Thames at Teddington), and it yields a net revenue that represents a return of nearly 45 per cent. per annum on its capital cost.

The completion of this canal was followed by that of the Lower Jhelum Canal, a similar, but much smaller, canal, which yields a net revenue return of more than 20 per cent. per annum of its capital cost.

Next followed the great Triple Canal Project, of greater magnitude and far

greater cost, but not nearly so remunerative as the Lower Chenab Canal. The Triple Canal Project was completed in about the year 1916 at a cost of about £6,900,000 (1,033 lakhs of rupees).

When fully developed it is expected to yield a net revenue return of about 8 per cent. per annum on its capital cost.

21. THE SUKKUR BARRAGE IRRIGATION PROJECT (1920).

The contemplation of these excellent results has encouraged the engineers and revenue officials of Bombay and Sind to put up a project, known as the Sukkur Barrage Irrigation Project (1920), which, according to its promoters, will easily put all other projects, present or past, whether in or out of India, in the shade, by comparison with its figures of cost, and the vastness of its scope.

My attention was drawn to this project, which has received the approval (subject to compliance with certain financial precautions) of the Secretary of State for India, by perusal of a report of a lecture delivered on the subject a year ago in London by Dr. Summers, C.I.E., the well-known expert irrigation engineer of Sind. So that when I was honoured recently by an invitation to discourse before this distinguished Society on the subject of "Irrigation Enterprise in India," I felt that I could not serve the Indian public and the Government of India better than by criticising the designs and estimates of this important project in the light of experience of perennial irrigation works in the past.

22. PHYSICAL CONDITIONS OF THE INDUS RIVERAIN.

The River Indus, from the point where it enters the Province of Sind (see Plate No. 1) 80 miles upstream of the rocky gorge at Sukkur, down to its mouths at the sea-coast about 400 miles downstream of Sukkur, lies along a ridge, alluvially formed by its own deposits of sediment, at an appreciable elevation (about 20 feet) above well-defined valleys, known as the East and West Nara, respectively, which lie, one on either side of it, at distances varying from 5 to 50 miles. These Nara valleys represent what may have at some period in the past been the bed of the river; and it is quite on the cards that the river may at some future period abandon its present elevated ridge and breach its way into one or other of the

PLATE I.

The River Indus and existing Canals of the
Province of Sind

lower lying valleys. (See Plate II, Fig. (a)). A brief reflection suffices to show that it is comparatively easy to irrigate from the river, in its high-water season, the greater part of the ridge of fertile soil that has been alluvially formed by the deposits of silt from its own floods in the past. And we find, as a matter of fact, that such irrigation has been practised in the past, from time immemorial, by the primitive devices of the local population; long before the British occupation of the country introduced some more scientific methods into their design, construction and control. The gross area of land thus commanded by existing irrigation canals in Sind amounts to nearly 18,000,000 acres; of which, it is reckoned, nearly 11 million acres represent culturable soil.

The area irrigated annually by the existing inundation canals of Sind amounts to about

3 million acres; or about, 27 per cent. of the estimated culturable area of the Province, and it is natural and intelligible that the Bombay officials should wish to double or treble, if possible, the area irrigated annually. But it is equally intelligible that their lack of experience of perennial canal irrigation may hide from their minds the natural limitations to any very great increase of intensity of perennial irrigation, in the peculiar alluvial formation to which I have drawn attention.

23. OUTLINES OF THE SUKKUR PROJECT (1920).

The Sukkur Barrage Irrigation Project provides for the construction of a barrage, or bridge-way fitted with sluice gates, across the River Indus at Sukkur, capable of holding up the water of the river to a level of 194.5 feet above the mean sea-level at

PLATE II

Cross-Sections of the Indus Valley

Fig. (b) - Latitude $26^{\circ}45'$ Fig. (a) - Latitude $27^{\circ}5'$ 

Karachi, for the purpose of irrigating the whole of the land on either side of the river, from Sukkur down to the town of Hyderabad. The gross area of land thus commanded by flow is estimated to amount to about $7\frac{1}{2}$ million acres.

The Sukkur Barrage Project aims at irrigating annually an area of 5,300,000 acres; rather more than the total culturable area of Upper and Lower Egypt combined; more than double the area irrigated annually by the Lower Chenab Canal, and nearly treble that of the Triple Canal Project. The estimated cost of the Sukkur Barrage Project is 1,842 lakhs of rupees (about £12,300,000); which is nearly seven times the actual cost of the Lower Chenab Canal, and nearly double the actual cost of the Great Triple Canal Project of the Punjab.

These data will suffice to give a fair idea of the magnitude of the Sukkur Barrage Irrigation Project.

The Report on the Project impresses me as being the work of a junior engineer of more than average industry, zeal, and ability. But no amount of natural ability on the part of an engineer can make

up for a lack of practical experience of perennial canal irrigation in the preparation of the designs, estimates, and financial forecasts of by far the greatest scheme of perennial canal irrigation that has hitherto been seriously put up for approval.

24. COMPARISON BETWEEN UPPER SIND AND MIDDLE EGYPT.

The River Indus and the Province of Sind have many points of resemblance, in physical characteristics, meteorology, etc., with the River Nile and Egypt.

Sind, like Egypt, is remarkable for the scantiness of its rainfall. The climate of Sind is much hotter than that of Egypt, but the rainfall of the latter country is even scantier than that of the former.

The Indus, from Sukkur to Hyderabad, a distance of 240 miles, resembles the Nile in Middle Egypt from Assiut to, say, Cairo (235 miles), in that it flows on an elevated ridge formed of its own alluvial deposits by spill; and in that it is flanked by lateral valleys at a lower level than its own marginal land.

PLATE III

Fig. (c) Cross-Section of Nile Valley at Minia (1908)

Fig. (d) Cross-Section of Nile Valley at Girga (1908)

And downstream of Hyderabad, down to the sea-coast, the Indus has the physical characteristics of the Nile in Lower Egypt.

There is in Middle Egypt an ancient channel, the Bahr Yusuf, which probably represents a former channel of the Nile, long since abandoned. The Bahr Yusuf runs roughly parallel to the Nile, at a distance of about five miles, but at a level (see Plate III., Fig. (c)) which enables it to act as a drain, and it has a separate outfall at a low level, into the depression known as El Fayum. Similarly, in Sind there is an ancient natural channel, the Narra (or East Nara), roughly parallel to the Indus, at a distance of about 50 miles from it, but at a level roughly 20 feet lower.

25. THE NARRA RIVER.

The Narra may represent a former channel of the River Indus; or it may even represent the long-lost *sixth* river of what is now known as the Punjab (Five Waters), but which might formerly have been called the "Chhe-n-ab" (Six Waters). The five existing rivers of the Punjab, viz., the Jehlam, the Chenab (Chhenab?), the Ravi,

the Bias, and the Sutlej, are known, in the reach below their final confluence, where they are united in a single stream, as the *Punjad* (Five Streams)—a word synonymous with *Punjab*. The perished River Narra (Nurra, or Nara), is known also in Sind as *Hukkra*; a name which is also applied in the Punjab to the "lost" river, which can be traced upstream (see Plate* IV.), through the deserts of Bahawalpur and Bikanir, to Hissar and the Nardak; where it may be identified with the Ghuggur, Chitang, and Saraswati, flowing from the direction of Thanesur—the sacred shrine of Kurukshetra, second only in sanctity to Hardwar, on the Ganges. It is conceivable, even, that the River Jumna flowed, at some remote period in the past, into the Indian Ocean, *via* the alignment indicated by the existing Saraswati, Hukkra or Narra, Channels, thus forming the *sixth* river of the Chhenab (now Punjab), before it, as the result of some extraordinary natural avulsion, turned away to the left and joined the Ganges to flow into the Bay of Bengal.

However this may be, the position of the Narra channel, relatively to that of the Indus, corresponds to that of the Bahr Yusuf relatively to that of the Nile in Upper Egypt. With this noticeable difference, however, that the practice, continued for centuries past, of "basin" irrigation in the Nile Valley, has had the effect of silting up the valley between the Nile and the Bahr Yusuf; whereas no such action has occurred between the Indus and the Narra.

26. COMPARISON OF THE INDUS WITH THE NILE.

The *average monthly* discharge of the Nile at Assiut ranges from a minimum of 21,000 cusecs in May up to a maximum of 325,000 cusecs in September; whilst the average yearly discharge is 107,000 cusecs.

The *average monthly* discharge of the Indus at Sukkur ranges from a minimum of about 20,000 cusecs in January-February, up to a maximum of 460,000 cusecs in August; whilst the average yearly discharge is 107,000 cusecs—the same as that of the Nile.

These figures indicate that the flood season flow of the Nile, though much less at its *maximum*, is more sustained, stately, and useful for irrigation than that of the

* Not reproduced.

Indus; which latter, with its more rapid transitions in magnitude of discharge, is more turbulent, unruly, erosive, and liable to change its course by sudden natural avulsion.

The ratio by volume, of the water-borne sediment of the Nile to the water bearing it, is, on the average of the whole year, $\frac{1}{1200}$ and in the months of August and September about $\frac{1}{530}$

The corresponding figures for the Indus are, on the average of the whole year, $\frac{1}{500}$ and in the month of August, $\frac{1}{400}$

These figures indicate more erosive currents in the Indus than in the Nile; and it is probable, at the same time, that the silt of the Indus is more sandy and less clayey—less fertile in fact—than that of the Nile.

27. OFFICIAL EXPERTS SILENT ON THE SUBJECT OF WATERLOGGING.

The subject of waterlogging has received scant attention from those responsible for the Sukkur Project (1920).

Almost the only reference to subsoil water levels in the Project report is the following reference to the Rohri Canal tract:—

“Very little irrigation from wells is practised, owing to great depth of subsoil water below ground level. Near the river this depth varies from 20 to 30 feet below ground. In the Jamrao tract it is from 20 to 35 feet; in Fuleli and Hyderabad from 30 to 50 feet. In Nasrat Canals district, except along the river banks, it is from 40 to 65 feet below ground.”

The higher official authorities seem to have been vague in their ideas on the subject. There was a conference of high officials held at Karachi on the 19th January, 1918, and at that conference, Sir Thomas Ward, Inspector-General of Irrigation in India, spoke as follows:—

“The (estimated) duty (of the water) must also be considered from the point of view of waterlogging. It is not possible, however, for me to give an opinion on this question. This must be left to people who know Sind conditions.”

This left the responsibility with the Bombay-Sind officials. Another conference

of officials was held at Government House, Karachi, on the 3rd February, 1919, under the presidency of the Commissioner. In the minutes of that conference the following is recorded:—

“Mr. Gebbie (Chief Engineer, Irrigation Works, Bombay) raises two points:—

“(a) Danger of waterlogging.

“(b) Minimum discharge of the River Indus.”

The conference then proceeded to discuss other matters, but avoided the subject of waterlogging. Whence it would appear that the Government of India is still without expert advice on this important problem.

28. THE SUKKUR BARRAGE PROJECT (1920).

The River Indus in Upper Sind, as we have seen, flows on an elevated edge of soft alluvial soil, formed by deposits of silt from its own flood-spills. Buckley, in his excellent treatise, “The Irrigation Works of India,” gives the following description:—

“Sind is an alluvial plain, almost every part of which has been swept by the Indus at some time or other. Traces of ancient channels are to be met with in every direction. The river has gradually worked its way from west to east. . . . The river more or less continually carries away its banks in one direction, and forms new land in another.”

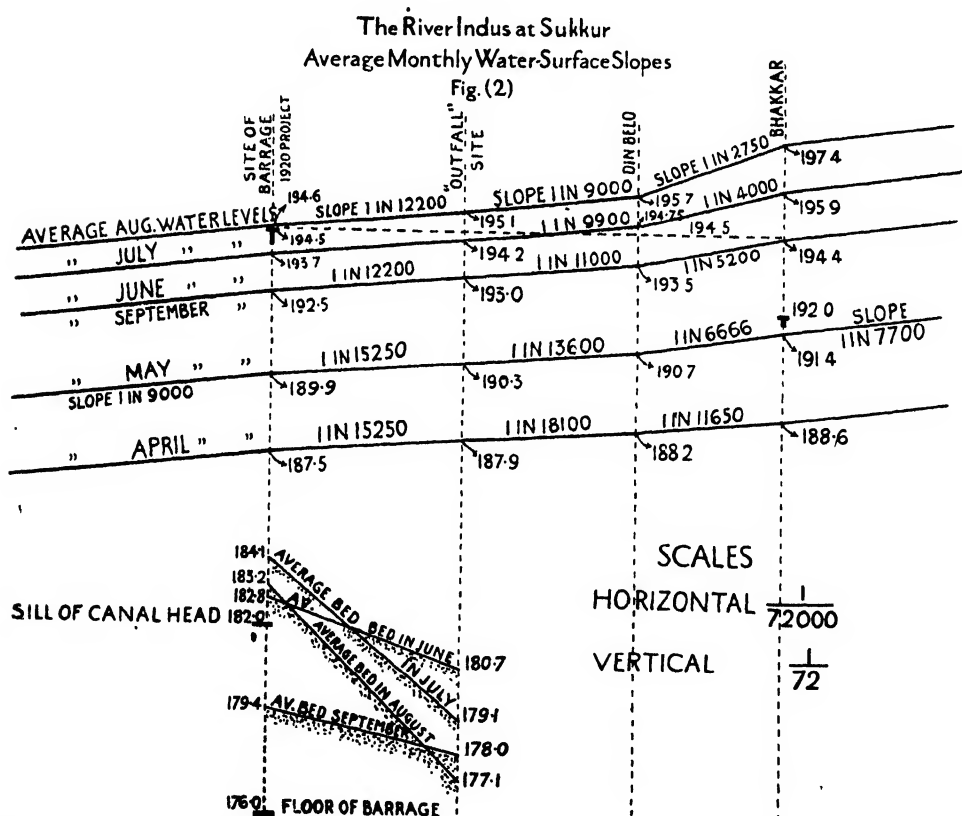

From time to time, during the past 70 years, projects for the control of the River Indus, for irrigation purposes, by means of a weir or barrage built across the river at Sukkur, have been mooted, considered, and rejected as unsatisfactory. All experts who have dealt with these projects in the past have been keenly apprehensive of the risk of the river's changing its course, and deserting the Sukkur gorge altogether as a consequence of any artificial obstruction offered to the river's flow there. The latest and best considered project was one prepared in the year 1911. In this project, which was, however, ultimately negatived, on the advice of a committee of experts whom the Secretary of State for India consulted for the purpose, the site proposed for the barrage was at Bhakkar, just upstream of the rocky gorge of Sukkur.

With a view of minimising obstruction to the river's flow, the level of the top of the gates of this barrage was fixed at 192 feet above mean sea-level at Karachi.

29. THE SUKKUR BARRAGE PROJECT (1920).

The authors of the Project of 1920 have been bolder (or rasher, as the case may be) than their predecessors. They propose to build the barrage at a site downstream of the gorge—about 3 miles downstream of the 1910

and that as the river is contained securely in high ground, between the gorge and the barrage-site, there can be no risk of the river abandoning its present channel by reason of interference with its flow through the barrage.

site—and to have the top of the gates at 194.5 feet above sea-level. They claim that the effect of the obstruction offered by the barrage to the flow of the river will not extend further upstream than the gorge;

In this belief they are mistaken. They appear to have been associating afflux with the maximum flood only. But Plate VI, Fig. 1, shows that the effect of ponding-up to 194.5 at the barrage in the month of May

will extend 16 miles up-stream of the barrage, and 13 miles up-stream of the gorge. This will cause shoaling up-stream of the gorge, which will obviously increase the risk of river-avulsion. See also, Plate VI, Fig. 2. The Barrage of the 1920 Project will interfere with and obstruct the flow of the river throughout the flood season, except in the month of August. The authors of the 1920 project have probably been driven to this risky expedient as a consequence of their decision to include in the scope of their project the irrigation at present effected from the canals on the right bank of the river at, and below, Sukkur.

The water surface of the river at *Bhakkar* is, throughout the four months, June to September, at, or above, the level 194.5, on the average; and the authors of the 1920 Project may have felt that they could not very well claim to be improving the condition of these canals, by means of the Barrage, unless they were able to claim that they would thereby be enabled to hold up the water to that level at all times, by means of the gates.

The fact that by holding up the river to the greatest practicable height they were able, at the same time, to *increase* (on paper) the area brought under flow by the North West Canal, as well as to *decrease the cost*, by reducing the depth of excavation, of all the canals, no doubt helped to decide them to adopt that feature of design.

The mean annual discharge of the Indus at Sukkur, is about the same as that of the Nile at Aswan; but the mean monthly discharge of the former river, is about 33 per cent. greater, at the height of the flood season, than that of the latter river. The Indus is, moreover, a more turbulent, and badly-behaved river, than the Nile.

The barrage across the Nile at Assiut has a waterway 1,832 feet wide; and it is designed to discharge the maximum flood under an afflux of five feet. The authors

of the Sukkur Barrage Project (1920), in their endeavour to pass the maximum flood of the Indus (assumed to be 1,500,000 cusecs) with an afflux not exceeding one foot, have designed their Barrage with a waterway 3,960 feet wide, and floor at 176 feet above mean sea-level. With this ample waterway they hope to escape the risk of the river changing its course, and deserting the Barrage on account of the obstruction to flow offered by it. But in dodging the Scylla of excessive afflux, they have drifted into the Charybdis of silt-trouble; which, in the end, will necessitate the creation of the excessive afflux which they have sought to obviate.

30. HYDRAULIC DATA OF THE INDUS NEAR SUKKUR.

In the Sukkur Project (1920), the Barrage is located about three miles downstream of the rocky gorge at which the Barrage of the 1911 Project was located; and about one mile downstream of the site known as the "Outfall," where accurate observations and studies of the river's hydraulics have been carried on weekly by the local engineers throughout the past 20 years, on the advice of the Indian Irrigation Commission of 1901. I cannot praise too highly the wise forethought of the Commission in giving that advice, or the labours of the engineers who have carried it out, and thereby given us a knowledge of local conditions which is of the highest utility.

The four months, June, July, August and September, are the months in which the water of the Indus carries its heaviest charge of silt in suspension; and they are also the months in which practically the whole of the irrigation of Sind is carried out under existing conditions.

The hydraulic conditions of the Indus, at the *Outfall site*, during these months, are as shown below:—

TABLE I.

Month.	Mean Monthly Water Level.	Mean Bed Level	Highest Mean Monthly Bed.	Lowest Mean Monthly Water Level.	Discharge (Cusecs).	Monthly Mean Velocity (feet per second).
June ..	193.1	180.7	183.7	191.8	230,000	5.3
July ..	194.1	179.1	181.6	192.8	310,000	5.9
August ..	196.0	177.2	179.7	193.8	460,000	7.2
September ..	193.6	177.0	180.8	191.1	266,000	5.4
Mean Averages	194.2	178.5	181.5	192.4	316,000	5.8

From statistics recorded by the Indus River Commission, it appears that the fall of water surface of the river, during these months, from the "Outfall" site to that of the *proposed Barrage*—a distance of 6,100 feet—is as follows :—
June—0.55 foot; July—0.62; August—0.65; September—0.43. Average 0.56, or, say, half a foot.

31. LEVELS OF THE INDUS AT THE 1920 BARRAGE SITE.

From the Report on the Project, it appears that the site of the proposed Barrage is that of a natural bar in the river bed, or of a shoal formed by material scooped out of the river bed upstream, by the currents rushing through the gorge, and deposited at that site ; and that the river bed is higher at the Barrage Site than at the Outfall Site, 6,100 feet upstream.

The following Table is furnished to show what the bed levels were at the Outfall and at the Barrage Site on certain dates :—

TABLE II.

Date.	Discharge.	Bed Level at at Outfall.	Bed Level at Barrage Site.	Rise.
31-7-18	261,000	177.89	180.28	2.39
17-7-18	403,000	174.61	180.17	5.56

From these data we may infer that the rise of bed level from the Outfall to the Barrage Site corresponding to other discharges would be for :—230,000 cusecs, 2.1 feet ; 310,000 cusecs, 5 feet ; 460,000, 6 feet. Whence we may deduce the hydraulic conditions at the Barrage Site, corresponding to those given in Table I. above, to be as follows :—

TABLE III.

Month.	Mean Monthly Water Level.	Mean Monthly Bed Level.	Discharge.	Mean Velocity.
June ..	192.55	182.8	230,000	5.0
July ..	193.48	184.1	310,000	7.0
August ..	195.35	183.2	460,000	8.0
September ..	193.17	179.4	266,000	4.0
Mean Averages	193.6	182.4	316,000	6.0

32. DESIGN OF THE BARRAGE (1920).

The authors of the Sukkur Project (1920), in order to give this Barrage ample water-way, put its floor level so low as 176.0 ; and with a view to excluding sandy sediment from the canal they designed the canal head with a masonry sill at 182.0, that is, 6 feet higher than the floor of the Barrage. They also provided in the design for moveable gate-cills, capable of rising, from behind

Fig. (3) Plan of Sukkur Barrage across River Indus

the masonry cill, to levels higher than 182 ; but these cannot come into action till the river water level rises appreciably above 194.0.

Now let us consider the conditions that will prevail at the site of the Barrage, and of the Rohri Canal Head, in the month of July and August. The plan of the locality will be as shown in Fig. (3) above.

Let X Y (Fig. (3) above,) represent the barrage in plan, and Y Z the Head Regulator of the Rohri Canal. Consider the current of the river flowing through the Barrage along the line A B C, and through the Canal Head along the line A B D. A section in the vertical plane, along the line A B C, will be as shown in Fig. (4) below:—

Fig. (4) Section through Barrage on line of flow (1920 Project)

Consider the average conditions of the months July-August. The mean level of the sandy bed of the river is 183.7, and of water-surface 194.4. The sand is lying 8 feet deep over the floor of the Barrage. The waterway being ample, there is practically no afflux at the Barrage; and therefore no force of current capable of scouring the sand down to floor-level 176.0.

Next consider a vertical section along the line A B D (Fig. 5).

Fig. (5) Section through Canal-Head on line of flow (1920 Project)

The sandy bed of the river is nearly two feet higher than the masonry cill of the canal head, and it is obvious that the current of entry will sweep large quantities of coarse bed sand from river into canal.

The movable gate-cill, behind the masonry cill, cannot be brought into action unless the river water surface is ponded up appreciably above 194.0 by the Barrage gates; and this will mean obstruction to the river's flow, and shoaling of river bed upstream. I calculate that the river water surface would have to be ponded up at least 4 feet, to level 198.5, in order to scour

the river bed down to level of Barrage floor, 176.0, and that the "backwater" caused by ponding-up would extend upstream to a distance of about 16 miles. In the conditions illustrated above what becomes of the "raised" masonry cill at 182? It is *submerged in the river sand; not raised above it!*

33. DESIGN OF ROHRI CANAL HEAD (1920 PROJECT).

Again, consider the current of entry into canal head. It may be regarded as in uniform flow, in 10 open channels of masonry, 25 feet wide and 11 feet deep.

11,000

Discharge per channel — = 1100 cusecs.

10

Mean velocity, 4 feet-seconds; Kennedy's 4.0

Critical Velocity Ratio = $\frac{4.0}{3.9} = 1.03 V_0$.

Whereas the corresponding ratio for the canal, with Kutter's $N = 0.025$, would be $0.62 V_0$ only; and the canal current, with 2.86 velocity, could not carry on the sand that would be brought into the canal with a current of velocity 4 feet per second.

Throughout the months of June, July and August, the sandy bed of the river will be at a level higher than the masonry cill of the canal head, and the canal is bound to silt heavily.

I have shown, in Appendix D., that if the value of Kutter's coefficient of rugosity in the canal should prove to be, as it is likely to be, 0.025 or higher, the water depth required in the canal will be 14.3 feet, or more; implying a water surface level in canal of 194.3, and in river 195.0. If silt be deposited in the canal, higher water levels than 194.3 will be required in the canal in order to discharge 10,992 cusecs. Efforts to keep the sandy bed of the river scoured down to level 176.0 may require ponding up of the river water surface to 199, or even 200. And this will be going on throughout the greater part of the months of June, July and August!

During these months the fall of water surface from upstream of the Sukkur gorge down to the Barrage Site is usually about 2.5 feet; but if the water surface of the river is held up five or six feet, at the Barrage Site (say, from normal 192.5 or 195.5 up to 199.5) for purpose of scouring river bed in front of canal head, the fall of water surface between Sukkur and the Barrage Site will be drowned out, through the greater

part of the months when the river currents are most heavily silt-charged; shoaling will be encouraged upstream of the gorge, and the risk of an avulsion of the river from its present course will be greatly increased.

The water surface slope of the river at the Barrage Site, in the months of June, July and August is about 1 in 10,000. That of the canal is designed to be much flatter, viz., 1 in 15,600. In the absence of any effective method of silt control at canal head, the canal is sure to get silted up.

34. THE BARRAGE WILL DISTURB THE RIVER'S REGIME.

The very amplitude of waterway provided for the barrage by the authors of the Sukkur Project (1920), though it will minimise the afflux caused by the barrage to *very great floods*, will aggravate silt trouble at canal-head, and necessitate a practice of continuous ponding-up of river flow throughout the monsoon season generally, which may eventuate in disaster. The entire design of the barrage, canal heads and canal head reaches, as presented in the 1920 Project, needs re-casting. *The full supply level of the canal must be lowered several feet below the 193.0 level fixed in the 1920 Project design.* This will not safeguard it from its liability to suffer from shoaling; but it will afford a margin of command, between river and canal, which may enable water to be passed into the canal over the shoal of sand deposited on its bed.

35. RATIO OF WINTER TO SUMMER IRRIGATED AREAS.

The authors of the Sukkur Project (1920), have designed their canals on the hypothesis that the area irrigated in the winter will be double that of the summer. By this means they are able to keep down the cost (on paper) of their project. But there is no justification, in past experience, for such a forecast of irrigation in land of deltaic formation; the physical conditions of the Indus Valley in Sind being similar to those of the Nile in Egypt, and of the canals in Madras and Behar in India.

36. INADEQUATE UTILISATION OF SILT-LADEN WATER.

By designing on the basis of a winter irrigation twice as great as the summer irrigation, the authors of the Sukkur Project (1920) refrain from utilising as much as

they might of the abundant summer flow of the Indus, with its rich burden of fertilising silt, and exhaust the scanty flow of the river in the winter, when it carries little or no silt.

37. OTHER CLAIMS TO A SHARE OF THE WINTER FLOW OF THE INDUS.

The winter flow of the Indus, at Sukkur, in the months of January and February is usually only about 30,000 cusecs; whilst in years of scanty flow it diminishes to about 20,000 only.

The perennial canals of the Sukkur Project (1920) have been designed with an aggregate capacity of 30,000 cusecs; so that they can take the whole of the winter flow of the Indus. But the area comprised within the scope of this Project is only 7,500,000 acres, gross; and, say, 6,000,000 acres, culturable. The gross area of Sind is, however, 18,000,000 acres, of which 11,000,000 are reckoned to be culturable, and available for irrigation. The remaining 5,000,000 acres of culturable soil in Sind, not provided for in the Project, are just as much entitled to a share of the winter flow of the Indus as the Project area; so the Project cannot be right in monopolising the winter flow as proposed.

Moreover, there are the claims of the Punjab to be considered. There is a tract of some five million acres of land lying on the left bank of the Indus, between it and the Jhelum and Chenab Rivers, the irrigation of which has been under consideration by the Punjab Government for 20 years past.

The mere fact that the Thal has vested rights in the winter flow of the Indus, superior to those of lands in Sind, further down the same river, further emphasises the unwisdom of designing the Sukkur Project canals to irrigate with a greater volume of winter flow than is absolutely necessary from the point of view of irrigation science and agriculture.

(To be concluded.)

PRODUCTION OF TURPENTINE AND ROSIN IN GREECE.—A note from the Greek Minister of National Economy (reported by the United States Consul-General at Athens) states that the collection of rosin from trees begins in Greece in May and lasts until September. The distilleries operate from June to March or April. The annual production of colophonum is about 4,000 tons, and of turpentine, 1,000 tons.

FRIDAY, JUNE 23RD, 1922.

IRRIGATION ENTERPRISE IN INDIA.

BY F. W. WOODS, C.I.E.,

Late Chief Engineer, Irrigation Department, Punjab.

(Concluded from p. 718)

38. VIEWS OF THE HON. MR. H. S. LAWRENCE.

The Hon. Mr. H. S. Lawrence, formerly Commissioner in Sind, and now Finance Member of the Bombay Government, wrote, with reference to the shortage of area cultivated in Sind in that year of drought and scanty river flow, 1918-19, as follows:—

“It is estimated that the summer harvest of food grains in Sind has decreased in area by 800,000 acres, or 33 %, and the outturn of the area cultivated has fallen short of the normal outturn by 400,000 tons of rice and millets ; and this winter harvest of wheat and pulses will fall short of a normal outturn by 100,000 tons ; i.e., a total reduction of food supplies of the Province from 1,100,000 tons to 600,000 tons. . . .

If the Barrage and the Main Canals

dependent thereon had been constructed, the position would have been very different. These canals are estimated to supply water for an annual cultivation of 2,700,000 tons (of food and cotton). Of these 2,700,000 tons, 900,000 would be on lands at present wholly uncultivated, and on lands already cultivated 900,000 tons would be rendered secure and another 900,000 tons would be new cultivation.

“In a year of distress like the present, the outturn and value of these safeguarded crops would be £13,500,000. This year a liberal estimate would place the value of the crops at only £3,500,000. Thus the surplus value of the crops that would have resulted from the existence of the Barrage would be £10,000,000. The cost of the Barrage and Canals combined has been roughly estimated at this same figure of £10,000,000. Thus, the whole of the capital cost would have been saved to the country by the harvest of this single year.”

This note of Mr. Lawrence's is impressive at first sight, but will not bear closer scrutiny. The value of the crops of Sind in the year 1918-19 was, not £3,500,000 only, but £5,600,000 ; and the cost of the Barrage and canals in practice would be nearer to £20,000,000 than to £10,000,000. The figures below are taken from the Administration Reports of the Province of Sind :—

TABLE IV.

Year.	Area Irrigated in Sind (acres).	Estimated Value of Crops Irrigated.	Value per Acre.
		Rs.	Rs.
1917-18	3,507,367	837,54,168	24
1918-19	2,630,776	846,47,368	32

The value of the crops raised during 1918-19 was actually greater than during the previous year. Mr. Lawrence would, no doubt, point to the fact that the area irrigated, and hence, presumably, the volume of

agricultural produce, was 876,000 acres less in the year of drought, 1918-19, than in the year of abundant rainfall, 1917-18 ; and would argue that such a fluctuation of results could not occur on a well-regulated

perennial canal system. He is apparently unaware that the area irrigated by the perennial canals of the Punjab, taken in the aggregate, was one million acres less in the year 1918-19 than in the following year ; and that the area irrigated annually by these canals during the three years, 1917-18 to 1919-20, varied over a range of nearly 30 per cent.

39. CRITICISMS OF THE ESTIMATES OF THE SUKKUR PROJECT (1920).

It is obviously impossible for me to discuss the whole project adequately within the limits of time and space which circumstances impose on me here. I will only briefly refer now to the salient features of the Project, leaving those who have time or inclination to consider the matter further to read my further discussions on the subject in Appendices which will be bound up with the printed report of the present discourse. The authors of the Project estimate that the same will be completed in the eleventh year after the commencement of construction, and that in the 21st year the area irrigated will amount to 3,741,000 acres ; and that 20 years later still, this area will have increased to 5,300,000 acres. In Appendices B, and E, I have discussed the matter, and arrived at the conclusion that the Project will not be completed till the 16th year, and that the area irrigated annually in the 26th year is not likely to exceed 3,700,000 acres ; which will anyhow be the limit of area irrigated annually. The authors of the Project estimate that the cost thereof will be about 1,600 lakhs of rupees. The Government of India have found it advisable to increase that figure to 1,842 lakhs (£12,300,000). In Appendix C I have discussed the matter, and arrived at the conclusion that the cost will probably not be less than 2,534 lakhs (£17,000,000). Additional reasons for my estimate of cost will be found in Appendix D.

In Appendix F I have criticised the Project forecast of probable Gross Revenue, and have come to the conclusion that the proposed barrage will not improve the conditions of the existing rice irrigation of the Indus Valley ; and that, therefore, although it may be permissible to charge the rice crop more for its irrigation than has been charged in the past, such enhancement of assessment should not be credited to the accounts of the Barrage Project

as, if fairly leviable, it will be leviable even if the Barrage be not built.

The provision for working expenses in the Sukkur Project (1920) in the 26th year is Rs. 50,28,000.

In Appendix G I calculate that this figure should be increased to Rs. 83,20,000.

The authors of the Sukkur Project (1920), as revised by the addition of 255 lakhs of rupees to the cost thereof by the Government of India, reckon that the Project will yield financial returns as follows :—

Period after completion.	Percentage on capital.
10th year	— 5.57%
20th „	— 8.97%
30th „	— 10.51%

Interest charges on borrowed capital being reckoned at 5 per cent.

My calculation, subjoined below, is that in the 10th year after completion (26th after commencement of construction) the nett revenue derived from the Project will be only 2.7 per cent. of the capital cost ; and that it will be 68 lakhs of rupees (£450,000) annually less than the interest charges on borrowed capital (interest reckoned at $6\frac{1}{2}$ per cent.).

40. FINANCIAL FORECAST, SUKKUR BARRAGE PROJECT (1920) RECONSIDERED.

I have calculated that the area irrigated annually by this Project will not amount to more than 3,700,000 acres ultimately. The waterlogging of the soil will prevent any further increase of area, by rendering large tracts of the country independent of canal water for winter cultivation. I have calculated also that the capital cost of the Project is not likely to be less than 2,534 lakhs of rupees, or £17,000,000.

My forecast, therefore, works out as follows :—

Capital Cost	Rs. 2534,00,000
Simple Interest at $6\frac{1}{2}$ % per annum	Rs. 164,70,000

Gross Revenue Receipts in the 26th year (10th year after completion) = 3,700,000 acres at Rs. 6 per acre	..	Rs. 222,00,000
Working Expenses at Rs. 200 per cusec of Canal Head Discharge	83,20,000

TOTAL NETT REVENUE .. Rs. 138,80,000

Deduct Nett Revenue earned
by the existing canals .. Rs. 42,00,000

Balance Nett Revenue due
to Sukkur Barrage Project Rs. 96,80,000

which is Rs.68,00,000 per annum less than
the interest charges on the capital borrowed.

41. AN ALTERNATIVE TO THE SUKKUR PROJECT (1920).

The criticisms, here presented, of the Sukkur Barrage Project (1920) would not be complete if I did not indicate, in some manner, however sketchy, the outlines of an alternative to that Project.

I would have no Barrage at all ; since, in this particular case, a Barrage seems to be a

to irrigate about 60 per cent. of this area annually ; or, say, 1,800,000 acres ; half in each season, viz., 900,000 acres in the summer, and the same in winter.

Allowing a cusec of full capacity for every 66 acres of summer irrigation, the discharge of the canal, at Head, would be 13,636 cusecs. The other features of design might be as follows :

Gradient = $\frac{1}{10,000}$; Kutter's $N = 0.025$;

Bed Width = 400 feet ; Water Depth = 11 feet ; Coefficient of Discharge = 92.3 ; Mean Velocity = 2.99 feet per second. Kennedy's Critical Velocity Ratio = $0.77 V_0$.

Wood's Silt Index = $\frac{2.99}{0.37 \times 11} = \frac{2.99}{4.07} = 0.74$.

needless and heavy item of expense. The Lower Swat River Canal, with Head at Abazai in the N.W. Frontier Province ; the Upper Jehlum Canal, with Head at Mangla in the Punjab (or, rather, Kashmir) ; and the Trebeni Canal in Behar ; are all examples of perennial canals which are fed from their parent rivers without the help of a barrage or weir across the latter ; and the same arrangement is practicable, at Sukkur, on the Indus, in Sind.

Consider the case of the proposed Rohri Canal. The longitudinal section of the alignment of the first 80 miles, or so, of this Canal, is shown in Plate V. According to the Sukkur Project (1920), the gross area commanded by this canal would be 2,956,518 acres. Suppose we were to arrange

The average water level of the Indus throughout the winter sowing season—October to December inclusive—is 187.5 ; and in the maturing season—January to March inclusive—it is 187.1.

At the site of the proposed Barrage, of the 1920 Project, the average water level is 186.8 in the sowing season, and 186.5 in the maturing season.

In this schema, (without Barrage) it will probably not matter much at which site the Rohri Canal off takes ; but I will take the least favourable condition by assuming that it will be at the lower site, where a winter water level of 186.8 on the average, in the sowing season, may be expected.

Suppose we fix the full supply level of the canal at 186.0 ; so that its bed level, at

head, would be 175.0. We might give the Head Regulator a waterway 800 feet wide..

The discharge per foot run of oill would be $\frac{13635}{800} = 17$ cusecs; and it would always be by "free" overfall over the top of movable gate-cills. The conditions of flow, in summer and winter respectively, would be as shown in Figs. (6) and (7) below:—

Fig. (6) Section through Canal Head on line of flow (Woods' Design)

The regulation of supply would be done by three tiers of gates in the summer, as shown in Fig. (6) above. The lowest gate would, in summer, always be resting on the floor of the Regulator; and the middle gate would also always be in the position shown, whenever the river water level is above 190.0. The top gate would pass down from above when required for use, and rise again from below, and the water would pass over its top by free overfall; and when the river is in high flood, above, say, 197.0, this gate could close the canal by abutting against a lintel at 196.0.

Fig. (7) Section through Canal-Head on line of flow (Woods' Design)

In the winter, all gates would be removed from the water, which would then flow into the canal, over the floor at 175.0, as shown in Fig. (7).

42. BRITISH IRRIGATION ENTERPRISE.

The vast and lucrative irrigation works which exist in most Provinces of India—the Periyar Dam and the Anicuts of Madras,

the notable Reservoir Dams of the Deccan and Gujarat, the Ganges Canal, the perennial canal systems of the Punjab, and the Inundation Canals of Sind—are monuments to the patient and intelligent labours of the British bureaucracy in India. Now that that bureaucracy is giving place to the new democracy, it would be satisfactory if these monuments of British enterprise could be handed over to the Indian public, as they are, with hardly a single failure amongst them. Before the Sukkur Barrage Project (1920) is put in hand, therefore, the Government of India would do well to subject it to closer scrutiny, than has hitherto been applied to it, with regard to:—

- (a) Risk of waterlogging of the soil.
- (b) Risk of silt-trouble in the canals.
- (c) Risk of shoaling of the river, and possible avulsion thereof, as a consequence of obstruction to its flow by the Barrage.
- (d) Risk of financial failure, resulting from under-estimation of cost of the Project; and over-estimation of its revenue receipts.

APPENDIX A.

THE AREA REGARDED AS CULTURABLE IN THE PROJECT.

The Project under consideration, which I may call briefly the "Sukkur Project, 1920," provides for the construction of a Barrage, or bridge fitted with sluice gates, across the River Indus, about three miles downstream of the rocky gorge at Sukkur; and for the construction of five canals, viz., three on the right bank, and two on the left bank, to take up and extend the irrigation of all the existing "inundation" canals that off take from the river, from just above the Sukkur (or Bhukkur) gorge, and the town of Hyderabad; a distance of 240 miles. The area commanded by direct gravitation flow from these canals will amount to about 7,500,000 acres; and the authors of the Project claim that 87 per cent. of this area, or, say, 6,500,000 acres, consist of good soil that is not only available for irrigation—not being taken up for other purposes, such as roads, canals, habitations, etc.—but is also culturable. *Prima facie* this claim seems to err on the side of optimism. In the tracts irrigated by the Punjab Inundation Canals, which are of alluvial formation, similar to that of Sind, the culturable area amounts to only 82 per cent. of the gross area (4,700,000 acres).

In the irrigated tracts of Madras, which are mostly of deltaic formation, out of a gross area of 7,100,000 acres, only about 70 per cent. (4,960,000 acres) is culturable and available for irrigation. It seems unlikely, therefore, that more than 80 per cent. of the gross area

comprised in the Sukkur Project can be reckoned upon safely as culturable and available for irrigation.

In the year 1910, in connexion with a previous project for the irrigation of Sind, a soil survey of the tract to be irrigated by the proposed Rohri Canal on the left bank of the Indus, was prepared by Mr. Lucas, I.C.S., a competent Revenue Officer, who estimated the culturable area there to be 2,120,000 acres. For the purpose of the 1920 Project, a fresh soil survey was ordered by the Government of Bombay in the year 1915; and Messrs. Baker and Lane were placed in charge of it. They increased Mr. Lucas' figure of culturable area by 380,000 acres: and it can reasonably be inferred that this difference of estimation by two sets of equally expert observers may have been due to the one estimate having been prepared in a spirit of caution and the other in a spirit of optimism. Similarly, in the case of the East Nara tract, Messrs. Baker and Lane, without having seen the tract, increased Mr. Lucas' estimate of its culturable area very considerably. Now, nothing is easier than for two or more individuals, or parties, to differ materially from each other in estimates of this nature; but the financial forecasts of a vast irrigation project ought not to be based on optimistic estimates. In a Report by Lieut. Fife, R.E., dated September, 1852, I find the East Nara tract described as follows:—

"The country, which is denominated the *Thurr*, is covered with enormous sandhills, extending on every side as far as the eye can reach, and presenting a singular but very desolate appearance."

The name *Thurr* (Thar), is the same as the name Thull (Thal), which is applied to the country between the Indus and Chenab Rivers further upstream, and implies bottom-land, interspersed with sandhills. In the Thal Canal Project of the Punjab the Chief Engineer, Punjab, reckoned for purpose of Project forecast, that only 50 per cent. of the gross area of the Thal is culturable. In the year 1910, Sir J. Benton, Inspector General of Irrigation, wrote of the East Nara tract as follows:—

"It has a high spring level, a sparse population; is unhealthy, and in many parts does not admit of intense irrigation."

On the whole, it cannot be regarded as prudent to reckon the culturable area of the Sukkur Project (1920) to be more than 80 per cent. of the gross area; or, say, 6,000,000 acres

APPENDIX B.

THE ANNUALLY IRRIGABLE AREA OF THE PROJECT.

INTENSITY OF IRRIGATION.

In the Punjab and in the United Provinces, the areas irrigated annually by the perennial canals bear the following percentage ratios to the gross area commanded by each canal:—

Canal.	Per cent.	Canal.	Per cent.
West Jumna ...	28	Sirhind ...	28
Upper Bari Doab	65	Lower Chenab	70
Lower Jhelum ...	58	Upper Ganges	24
Lower Ganges ...	15	East Jumna ...	29

In the Sukkur Project (1920) it is proposed to irrigate annually 71 per cent. of the gross area; an intensity of operation which has been approached only in the case of the Lower Chenab Canal. But the conditions of the Lower Chenab Canal are very different from those of the Sukkur Project. In the greater part of the tract irrigated by the Lower Chenab Canal, the subsoil water table was, before the opening of the canal, more than 100 feet deep below ground surface. It has risen 40 feet in 20 years, and is still a long way below surface; but the day will surely come, even though it be another 20 years distant, when the subsoil water will be so close to the ground surface in most places, as automatically to reduce the total area irrigated annually. Already in the upper reaches of the canal, where the spring level was, 20 years ago, about 40 feet deep below ground surface, it has risen so close to the surface that the cultivators have ceased to take canal water in the winter season. The same result is likely to follow closely on the heels of the Sukkur Project (1920), which proposes to irrigate tracts whose subsoil water level is generally less than 40 feet below ground surface, and in many places even 20 feet, or less. In the case of the Triple Canal Project of the Punjab, it was proposed to irrigate perennially from the Upper Chenab Canal all commanded areas whose spring level was deeper than 25 feet below ground surface. The spring level in these areas was usually more than 35 feet deep; but although the canal has been only a few years in operation, the spring level has risen so rapidly that everywhere it is now less than 25 feet below surface, and it has been found necessary to discontinue irrigation, during the winter, over a considerable proportion of its commanded area. So far as I can see, there is nothing to prevent a similar result in the case of the Sukkur Project (1920). If that occurs, it will be fatal to the Project, which depends mainly, for its financial success, on an area of winter irrigation double that which is designed to be irrigated by it in the summer.

In the case of the Upper Bari Doab Canal, in the Punjab, it has been found necessary to discontinue winter irrigation from the upper reaches of the canal (100 miles or so), with the result that the area irrigated by this canal, as a whole, is less in the winter than in the summer. In the tracts irrigated by the Lower Jhelum Canal, the rise of spring level since the opening of the Canal has been remarkably rapid; and, in fact, experience of perennial irrigation in the Punjab has been generally that the spring level is liable to be raised, by percolation

from perennial canal systems, at the rate of about two feet vertically per annum.

That experience indicates that it is inadvisable to allow winter irrigation to tracts in which the spring level is less than 25 feet below ground surface, and such irrigation is officially prohibited. The Sukkur Project (1920) ignores all this; doubtless in consequence of the Bombay engineers lacking experience of perennial canal irrigation.

In the case of the Triple Canal Project, which is the latest illustration of Punjab irrigation practice, the designs allowed for the irrigation annually, wherever spring level was deeper than 25 feet below ground surface, of 75 per cent. of the culturable area, or 63 per cent. of the gross area, after deducting from these areas the areas hitherto irrigated from wells. The Government of India should not allow the financial forecasts of the Sukkur Project (1920) to rest on a reckoning of an annually irrigated area greater than 60 per cent. of the total culturable area, or 50 per cent. of the gross area.

This will mean restricting forecasts to a reckoning of an irrigation of 3,700,000 acres annually, instead of the Project figure of 5,300,000. Even this figure is not likely to be worked to unless the area of winter irrigation is reduced to something equal to, or less than, the area of summer irrigation. For it is the winter irrigation mainly that waterlogs and impoverishes the soil, and throws it out of cultivation in consequence.

2. WATERLOGGING.

The evil of waterlogging, as a result of irrigation, is one which is seriously felt chiefly in tracts which are irrigated perennially, i.e., in the winter as well as in the summer. In tracts in which summer irrigation only is practised, the evil is not much in evidence, because summer irrigation is rarely practised for more than 4 or 5 months in the year; so that any soil which may become flooded or saturated during that period has an interval of 7 or 8 months during which the surface or subsoil water is able to drain off; and permanent stagnation of the subsoil water does not occur.

In the Punjab, the problem of prevention of waterlogging is always in the forefront of the minds of irrigation engineers, or other officials who may have to deal with irrigation; and it is with them a well-established principle that perennial canal irrigation shall not be introduced into a tract in which the spring level is less than 25 feet below ground surface. The importance attached by the Punjab Government to the subject is sufficiently indicated by its appointment, within recent years, of a Drainage Board, amply provided with funds, to formulate schemes for the prevention of waterlogging.

3. THE PRESERVATION OF WELL IRRIGATION.

In the Punjab it is also a well-established

principle that perennial canal irrigation shall not be introduced into a tract which is already irrigated to a great extent by wells: the idea being that well-irrigation tends to keep down the subsoil-water level at a safe depth; besides helping to maintain a good supply of draught-cattle.

The Bombay-Sind officials, however, propose to introduce perennial canal irrigation into tracts with spring level less than 25 feet below ground surface; and to throw the irrigating wells out of action; with the object apparently of showing, on paper, financial profits that in my opinion are not at all likely to materialise. In the Report of the Sukkur Project (1920) we find it stated, as regards the tracts on the right bank of the Indus:—

“DEPTH OF SUBSOIL WATER. This varies considerably in different parts of the tract. In Talukas, Kakkar, Dadu, Johi, and Sehwan, it varies from 20 to 25 feet or more. At present there is a fair amount of well cultivation in the *rabi* season.

In the Central Rice tract the subsoil water level is high, and wells are used for raising rice seedlings.

In the Northern *talukas* of the North West perennial area, the water level is much deeper, as much as 40 feet, and but little well irrigation is practised.

The wells will be useful for domestic supplies in future, but will hardly be needed for irrigation.”

4. LEVEL OF SUBSOIL WATER TABLE.

The soil of Upper Sind, as we have noted above, has been formed alluvially by deposit from the river's floods. That indicates that the ground surface is everywhere below High Flood Level. And as the subsoil water table is fed by percolation from the river, it follows that it cannot be far below ground surface. At present the subsoil water table slopes away on both sides from the river's edge (see Plate II, Fig. (a)); but when canals are in flow perennially, at distances of 10, 20, or 60 miles, from the river, and roughly parallel to its course, each of these canals will become a separate source of percolation flow to the subsoil water table, which will rise everywhere to within less than 10 feet below ground surface.

Plate III, Fig. (c) shows the subsoil water conditions in Middle Egypt; but the conditions in Sind will be much worse, because Egypt has safeguards which will not exist in Sind, viz:—

(a) The area irrigated in Middle Egypt in the winter is much less than it is in the summer; whereas in Sind, according to the Sukkur Project, it will be twice as great.

(b) The Bahr Yusuf is at a relatively low level, and acts as a drain to the subsoil water, but there is no corresponding provision in the Sukkur Project (1920).

(c) Much of the irrigation practised in Egypt, even from the perennial canals, is by "lift"; whereas the irrigation of the Sukkur Project (1920) is to be entirely by "flow," from elevated water channels.

5. PROPORTIONATE AREAS OF SUMMER AND WINTER IRRIGATION.

I have drawn attention to the similarity of physical conditions, as to soil and hydraulics, that exist between Sind and Egypt. The Sukkur Project (1920), however, draws no useful lessons from irrigation experience in Egypt. In Upper Egypt only 43 per cent. of the culturable area is allotted to perennial irrigation, and less than 20 per cent. of the culturable area is irrigated in the winter, or low-water season. In Lower Egypt about 27 per cent. of the culturable area is irrigated in the winter.

In Madras the area irrigated in the winter is insignificant; except in the Godavari delta; where, however, the winter-irrigated area is yet less than the summer-irrigated area.

There is, in fact, no justification in past irrigation experience, either in or out of India, for the supposition on which the Sukkur Project (1920) is based, that the winter-irrigated area, under this Project, will in practice be double the summer-irrigated area, in the ratio of $\frac{\text{winter}}{\text{summer}} \text{ irrigation} = \frac{54}{27}$ per cent. of the culturable area.

Even the Bombay Government seems to have been conscious of this, for in a letter dated 30th August, 1918, whilst approving of the intensities:—

Kharif ... 27 per cent. of culturable area.

Rabi ... 54 " " " "

it remarked that:—

"It was not expected that this area would be reached at any early date, but provision was to be made for it. In the final estimates only 27 per cent. of the culturable area would probably be estimated as rabi area."

The forecast of winter-irrigation from perennial canals, as set forth in the Project Report, must be reduced from 5,308,000 acres to 3,700,000 acres; by cutting out the 1,600,000 acres of winter-irrigation that will never materialise; or that, at any rate, will not do so within 10 years of the date of completion of construction. The perennial canals should, in fact, be designed to irrigate equal areas in the summer and winter seasons, and the financial forecasts should take into reckoning a winter-irrigation equal to about 27 (not 54) per cent. of the total culturable area, as was considered prudent by the Bombay Government even so lately as in August, 1918.

6. FORECAST OF AREA TO BE IRRIGATED EACH SEASON, ANNUALLY.

The authors of the Sukkur Project (1920) reckon that their Project will begin irrigation

in the seventh year after commencement of construction; that construction will be completed in the eleventh year; and that in the 21st year, 10 years after completion, the area irrigated will be 3,741,000 acres.

The existing canals on the right bank already irrigate 894,000 acres annually, out of which 575,000 acres are under rice, and will not be fit hereafter for anything but summer irrigation. Deducting these 575,000 acres from 3,741,000, we have left 3,166,000 acres, which, under the Project design are to be irrigated, 1,055,000 acres in the summer and 2,110,000 in the winter.

Thus the total summer irrigation will be, according to the Project, $575,000 + 1,055,000 = 1,630,000$ acres; as compared with 2,110,000 acres in the winter.

My opinion is that this forecast of 2,110,000 acres of winter-irrigation will probably not materialise; and that the winter area, will not be greater than the summer area (compare the West Jumna and Upper Bari Doab Canals); and that, therefore, the area annually irrigated, in the 10th year after completion, may not exceed $1,630,000 \times 2 = 3,260,000$ acres.

We may look at it another way. The Project forecasts an ultimate irrigation annually, in the 41st year, of 5,300 000 acres. Deducting 575,000 acres of rice from this, leaves us 4,730,000 acres, of which the forecast is $\frac{1}{2}$ summer, $\frac{1}{2}$ winter irrigation. Thus we arrive at:—

$575,000 + \frac{4,730,000}{3} = 2,152,000$ acres summer-irrigation, and $\frac{4,730,000 \times 2}{3} = 3,154,000$ acres

winter-irrigation. My view is that the winter irrigation will not exceed $\frac{4,730,000}{3} = 1,577,000$

acres; and that the area irrigated annually will not exceed $2,152,000 + 1,577,000 = 3,729,000$ acres—which is practically the same figure as stated in the Project for the 10th year after completion.

The letter, dated 30th August, 1918, quoted above, shows that the Bombay Government itself did not expect the area of winter irrigation to exceed that of the summer irrigation by the 10th year after completion; and my opinion is that no greater area of irrigation than 3,700,000 acres per annum can ever be expected from this Project.

I reckon that the Project will not commence irrigation till the 11th year; that it will not be completed till the 16th; and that the irrigation of 3,700,000 acres cannot be expected before the 26th. Beyond the 26th year no increase of irrigation can be expected, because the rise of spring level will render large acres independent of canal water for winter irrigation, even if it does not throw the land out of cultivation through waterlogging.

APPENDIX C.

THE PROJECT ESTIMATES OF COST.

A simple check on the sufficiency of the estimates of cost of the Sukkur Project (1920) may be found in a comparison with the figures of the Triple Canal Project, the latest irrigation work in the Punjab, completed in 1912-1915.

The Upper Chenab Canal and Lower Bari Doab Canal of that system from one combined canal, have a capacity at head of 11,700 cusecs. The revised estimate of its cost, direct and indirect, amounted to Rs. 596,85,426; or, say, *exclusive of cost of river works*, Rs. 500,00,000. This, *exclusive of river works*, is equivalent to a cost of $\frac{500,00,000}{11,700} = \text{Rs. } 4,274$ per cusec of full capacity at head. The authors of the Sukkur Project profess to have allowed in their Project for a rise in cost of labour and materials of 30 per cent. over pre-war rates. An increase of 30 per cent. on the cusec-rate of cost of the Upper Chenab Canal would raise it from 4,274 to 5,556 per cusec of capacity at head.

Let us compare this with the figures of the Sukkur Project

The figures of the proposed Rohri Canal of the 1920 Project are:—

Capital cost of Canal exclusive of barrage, direct and indirect Rs. 408,00,000

The head capacity of this canal is to be about 11,000 cusecs, so that its estimate of cost works out to Rs. 3,700 only per cusec of head capacity, instead of 5,556, as it ought to work out to.

These figures suggest that the estimate of cost of the Rohri Canal should be increased by 50 per cent., to make it a safe estimate.

Similarly, the estimate of cost of the Right Bank Canals of the Sukkur Project is as follows:

Capital Cost of Canal, direct and indirect Rs. 618,18,000

Head capacity=19,433 cusecs

Rate of cost per cusec=Rs. 3,181 only.

And in the case of the Nara Canal system:

Capital cost of canal, direct and indirect Rs. 239.92,000

Head capacity=12,200 cusecs.

Rate of cost per cusec=Rs. 1,967 only.

The authors of the Project claim that the rates of cost allowed in the estimates of the Right Bank Canals and the East Nara Canals, are 30 per cent. in excess of the rates allowed in the 1910 Project; but that, owing to economies of design, the excess has been reduced to 6 per cent. They have also gone on the assumption that the cost of remodelling an existing canal is only about one-fifth the cost of making a totally new canal of similar dimensions. These contentions cannot be admitted. My experience of remodelling existing canals has been, generally, that the remodelling may cost 60 per cent. of the cost of new construction, even in cases where the alignment is not altered.

If, however, we add only 50 per cent. to the cost of these estimates, as arrived at by comparison of the Rohri Canal estimates with those of the Triple Canal Project, *plus* 30 per cent., we arrive at the following result:—

	Ra.
Capital Cost, Direct and Indirect, exclusive of Barrage, Sukkur Project (1920)	1382,00,000
Add 50 per cent.	691,00,000
Total	2473,00,000
Add cost of Barrage (nett)	461,00,000
Grand Total	2534,00,000

2. ESTIMATE RATES.

The Government of India, before passing on the Project to the Secretary of State for India for sanction, increased the estimate of cost of ironwork of the Barrage, generally, from Rs.75,00,000 to Rs.200,00,000; and that for Plant from Rs.130,00,000 to Rs. 260,00,000; a total increase of 255 lakhs of rupees.

They overlooked the necessity of revising the rates for other classes of work; which can be seen, from the comparison, below, of the Project rates for the Barrage (1919), and Canals (1920), with the rates current in the Punjab in 1920:—

Class of Work.	Rates of Cost (Rupees).		
	Sukkur Barrage Estimate, 1919.	Sukkur Canals Project, 1920.	Punjab Rates, 1920
Concrete of Brick Ballast and Kankar Lime	—	32	35
Concrete of Brick Ballast and White Lime	17/8/-	26	35
Concrete Stone Ballast and Kankar Lime	—	25	35
Concrete in Cement Mortar	45	80	70 to 80
Random Rubble Masonry	27	30	45
Coursed Rubble Masonry	40	—	50

This statement shows that the current market rates in the Punjab in 1920 for these classes of work, were from 18 to 44 per cent. higher than the rates that have been allowed in the Sukkur Project estimates.

It is difficult to say what total difference in cost it would make to level up the Project rates to the Punjab standard; but the figures stated tend to shake confidence in the sufficiency of the Sukkur Project estimates.

3. HILL TORRENT WORKS, N.W. CANAL.

No provision has been made in the estimates of the Sukkur Project (1920) for the cost of works designed to pass the floods of the hill-torrents of the Baluchistan border across the North-West Canal. The proposal is to debit the cost of such works to a separate Provincial Fund, instead of to the Project estimate. This makes the Project appear (on paper) cheaper than it really is. It has been the established practice of the past, as, for instance, in the Ganges, Sirhind, Upper Jhelum, and other Canal Projects, to debit to the Project estimates the cost of all such Cross-Drainage Works; which has often been a very serious feature of expense. In the case of the Upper Jhelum Canal, the cost of the Cross-Drainage Works amounted to about 150 lakhs of rupees (£1,000,000), or rather more than one-third of the entire cost of the Canal system.

The Paharpur Canal, a canal somewhat similar to the North-West Canal of the Sukkur Project, but oftaking from the Indus some hundreds of miles further upstream, has proved a financial failure, by reason of the unforeseen magnitude of cost of its Cross-Drainage Works. In the case of the N.W. Canal, the authors of the Sukkur Project (1920) take credit for the revenue accruing from the extension of the Canal to command an area of 400,000 acres of new land along the Baluch border, but they shirk debiting the full cost of that extension to their Project. This is not right. The cost, which may, perhaps, amount to half a crore of rupees (say, £300,000), should be added to the Project estimates.

4. PROVISION FOR MAINTENANCE BEFORE COMPLETION.

It has been the established practice, in the past, to provide, in canal irrigation projects, for the cost of maintenance of canal works between the date of their completion and the date of commencement of irrigation and earning of revenue. No such provision has been made in the Sukkur Project (1920). That it ought to be made is obvious. In the case of the Triple Canal Project, the actual cost of this maintenance was, under pre-war conditions, 20 lakhs of rupees; equivalent, under post-war conditions, to 26 lakhs. This suggests that the corresponding provision in the Sukkur

Project (1920) should have been about 50 lakhs of rupees, or, say, £300,000.

5. PROBABLE TOTAL COST.

There are other numerous instances of omission, or of under-estimation, in the estimates of the Sukkur Project (1920), which need not be described in detail, but which all support the general conclusion that the total cost of the Project, instead of being put at 1,600 lakhs of rupees, as stated by the Government of Bombay, or at nearly 1,842 lakhs (£12,300,000) as revised by the Government of India, ought really be increased to at least 2,534 lakhs, or, say, £17,000,000; reckoned at the exchange rate of sixteen pence per rupee.

APPENDIX D.

1. CANAL DESIGNS—KUTTER'S COEFFICIENT.

The canals of the Sukkur Project (1920) have been designed on a uniform system. We may examine the design of the proposed Rohri Canal in its head reach, as typical of all.

Rohri Canal.

Discharge=10,992 cusecs. Gradient 1 in 15,600. Bed-width, 253 feet. Full water depth, 13 feet. Kutter's $N=0.020$. Mean velocity, 3.26 ft. per second. Kennedy's critical velocity ratio, 1.002.

The value of Kutter's co-efficient is not likely, in practice, to be so low as 0.020. In the Punjab, the practice has been, for 20 or 30 years past, to design main canals on the assumption that $N=0.0225$.

In the Triple Canal Project the value of N was at first put inadvertently at 0.020, but the error was rectified before the canals were completed.

In practice, the main perennial canals of the Punjab exhibit in their head reaches even greater rugosity than is implied by $N=0.025$. Careful hydraulic surveys have established the average value of N in the following canals, thus:—

West Jumna Canal—Dadupur to			
Indri	$N=0.031$
Upper Bari Doab Canal—Tibri to			
Aliwal	$N=0.027$
Lower Chenab Canal—First 16			
miles	$N=0.027$

The soil of Sind is said to be lighter and more friable than that of the Punjab, but even if it be not, it is quite on the cards that the canals of the Sukkur Project may exhibit a rugosity implying that $N=0.027$. The relative narrowness and great depth of the Rohri Canal (as per Project, 1920) will aggravate the tendency of the sides of the canal to cave in by erosion, thereby increasing its rugosity. Even if we credit it with a rugosity no worse than $N=0.025$ the design will be affected as follows:—

Bed width=253. Water depth=14.3. $S=0.00064$. Kutter's $N=.025$. Mean velocity=2.86. Discharge=10,931. Kennedy's critical

2.86

Velocity ratio = $\frac{2.86}{4.6} = 0.62$ Vo.

4.6

2. SILTING OF CANALS PROBABLE.

This means that the mean velocity of the current, instead of being equal to Kennedy's Critical Velocity, would be only 62 per cent. of that velocity; and the chances of the canal suffering from silt deposits would be far greater than supposed by its designer.

Again, the water depth required for a discharge of 10,992 cusecs would be rather more than 14.3 feet; so that, with bed level at 180 feet above mean sea-level, the full supply level of the canal would be at 194.3, instead of at 193.0 as designed. And this would require a water level of about 195.0 in the river; whereas the top of the barrage gates will be at R.L. 194.5 only.

If the canal suffers from silt deposits, as it probably would, with mean velocity=0.62 Vo only, even higher water levels will be required in canal and in river, in order to force 10,992 cusecs over the shoal, or silt-deposit, in the canal.

These remarks suffice to show the defective nature of the designs of the Sukkur Project (1920) Canals.

In order to obviate the inconvenience of heading up the river water surface above 194.5, so as adequately to feed the canals, it will be necessary to make the Rohri Canal wider than it has been designed in the 1920 Project, and at a lower level. And this will mean additional expense, which must be added to the provision in the estimates.

The other designs are open to the same objections, except that the cases of the Central Canal on the right bank, and also of the East Nara Canal, will be worse, since they are designed with full supply level at 194.0, and might need a water level of 196.0, or higher, in the river, in order to feed them adequately.

In assuming that Kutter's N for their canals will be so low as 0.020, the authors of the Project have been guided probably mainly by an impulse to keep down the cost of the canals *on paper*. They rest this figure on an Inspector-General's order dated January, 1907; which, however, was superseded by a subsequent order issued in the Punjab, by the same authority. In any case it is impossible for any expert to deny that the Sukkur Canals may have a coefficient of rugosity as high as 0.025, or even 0.027, in their head reaches; and no design should be passed which does not allow a sufficient margin of command, between river water level and canal water level to ensure complete supply to the canals at all times and under any probable adverse conditions.

In the 1920 Project the new Nara Canal has been designed with bed width 350 feet and water depth 11.5 feet; and it is not apparent why the Rohri Canal has been designed so much narrower and deeper.

In my opinion a bed width of about 400 feet and water depth of about 10 feet would be more suitable in either case.

3. LOSS OF "HEAD" IN ENTRY.

The 1920 Project assumes that the loss of head of water between river and canal will be only 0.3 foot; but this is only another instance of undue optimism. In the summer the river will be flowing past the canal head, at right angles to the direction of the canal, with a mean velocity of six or seven feet per second. In order to enter the canal the current will have to swing round through a quadrant; it will strike the piers of the canal head obliquely, and the disturbance set up will be such that the loss of head in entry cannot safely be put at less than, say, 0.7 foot.

APPENDIX E

DURATION OF EXECUTION OF THE PROJECT.

The authors of the Sukkur Project (1920) forecast that its construction will be completed within 12 years. This is too optimistic.

The Lower Chenab Canal, in the Punjab, has a head discharge of about 10,700 cusecs, and it took about 12 years, reckoning from commencement of the head works, to complete that system. Similarly, it took 12 years to complete the combined Upper Chenab and Lower Bari Doab Canal, which has a head discharge of 11,000 cusecs.

The Sukkur Project comprises five separate canals, with discharges as follows:—

Rohri=10,992 cusecs; East Nara=12,200; Right Bank (Central)=12,350; North West=4,300; South East (right bank)=2,800 cusecs.

It seems clear that it will take much longer than 12 years to complete all these canals, whose aggregate head discharges amount to 42,600 cusecs.

There are several reasons which militate against the likelihood of rapid progress of construction on the Sukkur Project. At the time the Lower Chenab Canal was under construction there was no other irrigation work of great magnitude under construction in Northern India; and so that canal had command of the entire labour market of Northern India and Afghanistan and Baluchistan.

The same was the case with the Triple Canal Project, when it was put in hand later on. But the Sukkur Project will have many rival schemes of construction competing with it in the market for labour and materials. Amongst these may be mentioned the Sutlej Valley Canals Project in the Punjab, estimated to cost 1,400 lakhs; and another Project of similar magnitude in the United Provinces.

The labour market has, moreover, been depleted, since the construction of the Triple Canal Project, by the severe malaria epidemic of the year 1917, the calamitous influenza epidemic of 1918, and the Great War of 1914-18. Taking all this into account, it seems likely that it may take 20 years to complete the Sukkur Project (1920); and, at any rate, the period cannot reasonably be put at anything less than 16 years.

APPENDIX F.

GROSS REVENUE RECEIPTS.

I have calculated, elsewhere, that the annually irrigated area, which has been estimated in the Sukkur Project to amount to 5,300,000 acres in the 40th year after commencement of construction, is never really likely to exceed 3,700,000 acres. And if we allow that it is possible to complete the Project within 16 years, we may infer, from experience in the Punjab, that the irrigated area in the 26th year (10 years after completion), may amount to 3,700,000 acres; though it is not likely to be fully developed by that time. Moreover, the revenue calculations should show a deduction for *Kharaba* remissions, and remissions under Tenancy Rules.

It is stated, in the Sukkur Project Report, that the area at present irrigated in the tracts comprised in the Project is 2,035,636 acres; and the revenue assessed on that area amounts to Rs. 61,51,691; or to about Rs. 3/- per acre. It is estimated that the canals of the Project will begin to irrigate in the 7th year from commencement of work, and that in that year the area irrigated will increase to 2,240,142 acres, whilst the revenue will jump up to Rs. 99,67,631, implying an average rate of 4/8/- per acre. The increase of area of new land irrigated will be only about 204,000 acres, whilst the increase of revenue is put at Rs. 38,00,000. This is not a reasonable forecast. It will not be practicable to increase the assessment, on the existing irrigation of two million acres, so suddenly as that. The increase will have to be far more gradual. This applies to irrigation other than that of rice. In the case of rice-irrigation, it is difficult to credit the Barrage Project accounts with any increase of assessment. Consider the case

of the Right Bank Canals, which at present irrigate about 900,000 acres annually, mostly rice. The Barrage will not in any way improve the water supply for rice-irrigation, but, on the contrary, it will reduce the abundance thereof.

The average water surface levels of the Indus during the monsoon months, at the Bhakkur gorge are:—June, 194.5; July, 196.0; August, 197.5; September, 194.4.

The Barrage, three miles further down the river, will give the Canals water levels ranging from 193 to 194 only. This is no improvement on the conditions of the existing canals, which offtake at Bhakkur, but a change for the worse.

It is true that the Barrage will give higher water levels in April, May and October than the existing levels, which range from 188.5 to 191.5; but this will not help the rice crop, which does not need irrigation before June nor after September.

How, then, can the Barrage be fairly credited with the proceeds of an increased assessment of revenue on rice irrigation? If it be fair to increase that assessment, and if the rice crop can afford to pay that increased rate, the increase can be imposed now, whether the Barrage be built or not. The amount of the increased assessment cannot fairly be credited to the Barrage Project as an asset that can be created only by means of the Barrage.

We may concede that it will be permissible to levy the enhanced assessment of Rs. 6/- per acre on all existing irrigation with effect from the 26th year after commencement of construction; but the enhanced assessments on rice, at least, and on all June-September crops, should be treated as existing revenue, and not treated as an asset of the Barrage Project Accounts.

APPENDIX G.

WORKING EXPENSES.

The Sukkur Project (1920) aims at constructing canals modelled on the Punjab perennial canal pattern; but it reckons Working Expenses to amount to only Rs. 1.25, or slightly less, per acre irrigated annually. This calculation is not justified by Punjab experience, the cost of working the Punjab canals being as follows:—

TABLE V.

Canal.	Area Assessed (Acres).	Working Expenses (Rs.)	Cost per Acre Assessed (Rs.)	Canal Head Discharge. (Cusecs.)	Cost per Cusec of Discharge. (Rs.)
West Jumna	746,000	15,36,000	2.06	6,400	240
Sirhind	1,293,000	20,50,000	1.59	8,500	241
Upper Bari	1,123,000	13,94,000	1.24	6,700	208
Lower Chenab	2,347,000	23,54,000	1.00	10,700	220
Lower Jhelum	778,000	9,29,000	1.20	4,000	232
Upper Chenab }	1,071,000	24,05,000	2.24	11,700	206
Lower Bari }	634,000	11,23,000	1.77	6,750	166
Averages			1.59	7,820	216

The average cost per acre assessed annually, for all these canals, works out to Rs. 1.6 per acre; but the authors of the Sukkur Project (1920) provide for working expenses at the rate of Rs. 1.25 per acre only. They forecast that the area irrigated in the 26th year will be 4,060,000 acres, and the Working Expenses Rs. 50,28,000. If they had calculated the latter at the 1.6 rate their estimate of expenses would have amounted to 65 lakhs of rupees per annum, instead of 50 lakhs only. Whilst, if they had taken their rate of cost at Rs. 2/- per acre (as obtained on our latest Punjab Canals, the combined Upper Chenab and Lower Bari) their Working Expenses would figure out to Rs. 81,20,000 in the 26th year.

On the whole, it seems soundest to estimate the Working Expenses thus:—

the canals. The outstanding interest of the paper was the author's views on the proposed Sukkur Barrage. That project was mooted during the time he (the Chairman) was Governor of Bombay, between 1903 and 1907, and he was optimistic enough to think that a start might be made on the work before his term of office expired, but up to the present nothing had been done. A year ago he had the honour of presiding at a lecture, delivered by Dr. Summers before the East India Association, which was confined entirely to the Sukkur Barrage, and all who took part in the subsequent discussion agreed with the views of the lecturer. Dr. Summers's conclusions seemed to be so reasonable that he felt there must be some extraordinary error of judgment on the part of those at the present time who were responsible for

TABLE VI.

Canal.	Canal Head Discharge (cusecs).	Rate per Cusec. (Rs.)	Working Expenses in 26th year. (Rs.)	Area Irrigated (Acres).	Cost per Acre (Rs.)
Rohri	11,000	225	24,75,000	14,00,000	1.77
East Nara	12,200	200	24,40,000	10,00,000	2.44
Right Central	12,350	154	19,00,000	4,70,000	4.0
Right N.W.	4,300	220	9,45,000	5,40,000	1.75
Right S.E.	2,800	200	5,60,000	2,90,000	1.9
	42,650	200	83,20,000	37,00,000	2.24

which amounts to 33 lakhs of rupees per annum in excess of the provision in the estimates of the Sukkur Project (1920.)

Looking at the matter in a broad common-sense way, we see from Table V. above, that the Lower Chenab Canal, with a Head Discharge of 10,700 cusecs, costs Rs. 23,54,000 annually to maintain; and there is no very apparent reason why the proposed Rohri Canal, with a Head Discharge of 11,000 cusecs, should cost only Rs. 17,59,000 annually to maintain, as is calculated in the Sukkur Project (1920).

Similarly, the East Nara Canal, with 135 miles length of Supply Channel in the conditions of a natural river, will require enormous expenditure on maintenance and improvements, as part of a perennial canal system. Its conditions will be somewhat like those of the West Jumna Canal, only worse.

DISCUSSION.

THE CHAIRMAN (Lord Lamington), in opening the discussion, said it might appear to be exceedingly easy to irrigate land by means of water from a canal, but many people did not take cognisance of the difficulties connected with the water-logging of the land and the silting up of

suggesting that the Sukkur Dam should be built before trying the far simpler project of cutting the canal as described by Mr. Woods. To the best of his knowledge, the Secretary of State had never advanced a single argument on any occasion in favour of commencing the building of the Sukkur Barrage, before trying the far simpler, cheaper and almost immediately remunerative work of cutting the canal. Of course it was impossible to say what a river would do once its water supply was tampered with, and it might be necessary subsequently to build a barrage, but why one of the biggest engineering projects ever placed before the world should be begun before the far less costly project referred to was impossible for him to understand.

THE SECRETARY of the Section read the following message from Lord Sydenham:—

"I deeply regret that pressure of work prevents my being present. I have stated my views of the 1920 Project plainly in the House of Lords. This Project is one which I, as Governor of Bombay, would never have approved. I think that Dr. Summers has conclusively shown that it is radically unsound financially, and that if carried out the effects will be disastrous."

SIR LIONEL M. JACOB, K.C.S.I., late Secretary to the Government of India, in the Public Works Department, said that he was quite sure that all engineers interested in irrigation, and all those interested in the welfare of India, particularly of Sind, would welcome the paper by Mr. Woods, a scientific engineer of reputation, one who had devoted many years of his service to a study of the very engineering problems which had an intimate connexion with the Sukkur barrage project. Personally, he (the speaker) had already given his professional opinion on the scheme in the course of the discussion on Dr. Summers's lecture on the same subject. He then said, on the information given by Dr. Summers, that he was convinced that the project had been hopelessly under-estimated in cost, just as hopelessly over-estimated in revenue receipts, and that there were many serious engineering defects which might conceivably cause an avulsion of the Indus and a calamity of first magnitude. He was, therefore, very anxious to hear the views of Mr. Woods, who had taken no part in the previous controversy. He could have wished that Mr. Woods had been able to convert him to the idea that the project was a good and sound one in the interests of India. But on the contrary, he was only confirmed in his former opinions. It was now quite clear to him that the estimate was over sanguine both in the matter of expenditure and of revenue, and that the barrage and the canals were of such faulty design that the latter must silt very badly. And if an endeavour were made to force water over the silt by further heading up of the water at the barrage, there would be such an afflux above the Sukkur Gorge that the Indus might abandon its present course. No provision was made in the estimate for protecting the river against a disaster of this kind, and avulsion meant grave damage to the North-Western Railway, and to many canals on which the cultivation of a rainless country was dependent. The prospect was consequently very serious, and the only safe course of action was to revert to some such canal as was designed by Dr. Summers in 1910, and to some such revenue forecast as was prepared at that time by Mr. Lucas, Commissioner in Sind, a head being provided for the Rohri Canal on the principles that Mr. Woods had explained. He thought that on the whole, the author had been indulgent to the project, and that he might have been more severe. But at any rate Mr. Woods had prophesied that instead of the work proving productive, it would cause a loss of 68 lakhs of rupees, about £450,000, a year. India was now faced with a very serious budget deficit, the people were complaining of over-taxation, and though the country was very lightly taxed as compared with England, the position was sufficiently grave to cause the appointment of a Retrenchment Committee, with Lord Inchoape as chairman. In view of these facts, he asked whether the present

was a suitable time for the Government to embark on a project which could only lead to financial disaster. If it were only a question of pecuniary loss for the sake of the indirect benefits to Sind, his mind would be easier, but even so, it was desirable not to waste money. It was, however, much worse than that. It was not merely a case of monetary loss. The canals as designed would not do the work expected of them; if they did they would water-log the country and injure the health of the people and the quality of the soil, and always in the background was the menace to the integrity of the Indus. He hoped that the Government would take a warning from the facts brought to notice by the author of the paper.

MR. SIDNEY PRESTON, C.I.E., C.B.E., said he was greatly complimented in being asked to join in the discussion. It was perfectly true that a good many years ago he had a great deal to do with Indian irrigation, but he had been retired 17 years, during which time he had not been connected with any of the big schemes for irrigation in India. He thought a more appropriate title for the paper would be "The Sind Canal" instead of "Irrigation Enterprise in India," because the whole of the paper was practically a diatribe against the project which had been sanctioned by the Secretary of State. He was not qualified to offer an opinion one way or the other in reference to the project in question, because he had not seen any of the plans or estimates. It was obviously an extremely complicated problem, and he could not possibly jeopardise any reputation he might have as an irrigation engineer by offering any opinion in reference to it. He had a sort of feeling, however, that as a rule the authorities were right. Dr. Summers prepared a Sind irrigation scheme which was considered by the Secretary of State and by a committee of experts, and it was turned down. Subsequently another scheme was prepared, he believed by Mr. F. St. J. Gebbie. The 1920 project was then prepared and carefully considered by all the responsible engineers, including the Inspector-General of Irrigation. It came home to the Secretary of State, was considered in England and subsequently sanctioned, and as far as he knew in due course it would be carried out. He was bound to confess that until he heard what the projectors of the 1920 Project had to say he had a feeling that the Secretary of State must have had some reason for sanctioning the scheme. He was asked to join in the discussion on the paper read by Dr. Summers, before another Society, but declined to do so for the same reason that he refused to give any opinion at the present moment, namely, because he knew nothing whatever about the project. He very much regretted that at the meeting referred to, while a good deal was heard from Dr. Summers and

those who supported him, nobody responsible for the Project appeared and spoke in favour of it. He hoped that would not be the case on the present occasion.

DR. T. SUMMERS, C.I.E., D.Sc., M.Inst.C.E.T. said he had fully described his project in the lecture he delivered a year ago, and he would, therefore, not repeat the particulars on the present occasion. He only desired to say that Sir Sydney Crookshank, Secretary to the Government of India, had lately put up a defence of the 1920 Project in 12 columns of the *Pioneer*, and at the end of that defence he remarked that the statements of the opponents of the 1920 Project should not "*be accepted without examination in the hard light of facts*." That was all that those who opposed the 1920 Project asked for—an examination of the whole subject.

COLONEL SIR CHARLES E. YATE, Bt., C.S.I., C.M.G., M.P., in proposing a vote of thanks to Mr. Woods for his valuable paper and to Lord Lamington for presiding, said he was sure it would be agreed that the paper would have very important and far-reaching effects. The author, who until recently was Chief Engineer of the Irrigation Department in the Punjab, had worked on the Indus and its tributaries for the best part of his life, and he had just come home from the Punjab with an even later experience than that possessed by the expert committee which reported on the 1920 Project. He hoped the author's opinions would receive the consideration they deserved, as the subject with which the paper dealt was one of vital importance to India.

MAJOR-GENERAL BERESFORD LOVETT, C.B., C.S.I., in seconding the motion, said he had a knowledge of the Indus which went back for 60 years. At one time he was deputed to carry out a project for the protection of the town of Dera Ismail Khan on the Indus, which was gradually being swept away house by house. The protective works erected were successful. In due course he received a vote of thanks from the Government for causing the Indus to retreat seven miles, the town thus being saved; but this shewed that the vagaries of the Indus alluded to by Mr. Woods in his informative address, existed wherever the banks were not solid rock.

The motion was carried unanimously.

MR. WOODS, in reply, said that he would have welcomed more in the way of opposition, or of adverse comment on his criticisms, from those who might be disposed to disagree with them. Mr. Preston had said that it seemed to him that the paper had been rather more in the nature of a diatribe against the Sukkur Barrage Project, in particular, than a review of Indian irrigation enterprise in general.

To that Mr. Woods would reply that, whilst he trusted his criticisms had been couched in language of propriety, it was evident at this juncture that no review of Indian irrigation enterprise would be complete, or even adequate, if it failed to discuss the salient features of the latest manifestation of such enterprise, as embodied in the Sukkur Barrage Project of 1920. The mere fact that the capital cost of this Project was likely to exceed the aggregate capital cost, down to date, of all the perennial canals of the Punjab, was sufficient to justify the most careful examination of its provisions; whilst the extent to which these provisions ignored the teachings of past experience, rendered it all the more advisable for the reader of the paper to draw a clear line of distinction between the successful irrigation enterprise of the past, and that which was likely to be a disastrous failure if persisted in hereafter.

Mr. Preston had pointed to the fact that the Sukkur Barrage Project had been approved of by the Government of India, on the recommendation of its expert advisers, and subsequently sanctioned by the Secretary of State for India; and he naturally attached importance to these circumstances. He (Mr. Woods) had in his paper remarked, however, that this particular Project had been prepared by engineers who had no personal, practical experience of the design, construction, or control of perennial irrigation canals, and, so far as was known, the only engineer with knowledge of perennial canal irrigation who had approved of the Project was Sir Thomas Ward, who had expressly disclaimed responsibility for some of the most important features of the same.

In any case Mr. Woods had criticised the Project adversely on specific professional grounds, and he would welcome any authoritative attempt to meet his criticisms.

The Secretary of State for India had no expert advisers on irrigation matters on his staff, and it was understood that he did not consider himself called upon to judge of the technical merits of an irrigation Project, the funds for which could be raised by the Government of India to his satisfaction. In conclusion, Mr. Woods thanked Sir Charles Yate and General Beresford-Lovett for their appreciative comments; and especially thanked Lord Lamington for again demonstrating his keen interest in Indian public affairs by taking the chair on this occasion. He was grateful also to all those present at the meeting for their patient endurance of his somewhat lengthy discourse.

The meeting then terminated.

SIR JAMES WILSON, K.C.S.I., writes:—

I am not a skilled engineer, and it is thirteen years since I left India; but during my service I had greater occasion than most Civilians have to study irrigation questions, and I have kept in touch to some extent with recent developments,

So I may perhaps make bold to put forward some of the conclusions which I have reached after much thought on this very important subject. I confine my remarks to irrigation in the Indus valley.

In my time there was a tendency to consider irrigation schemes piecemeal, which sometimes led to the adoption of short-sighted views and of schemes which failed to make the best use of the water available in the interests of future generations. I suggest that if this has not yet been done, a very large contoured map should be made, including not only the whole Punjab, but the whole Indus Valley down to the sea, and a great part of Rajputana. On this map should be marked for each of the great rivers the highest point at which the construction of a weir would be feasible, noting (1) the average winter supply, and (2) the average summer supply at that point. Then, disregarding all Provincial and State boundaries, as well as existing canals, mark on this map the limit of possible command from one or other of the rivers, and think what an engineer could best do with the water available if he had a clean slate to work upon. The general position is this—an immense quantity of water flows uselessly into the sea down the valley of the Indus and its tributaries, while the whole of the winter supply and a great part of the summer supply might be utilised to irrigate vast areas of land in and between and beyond those valleys, which only requires moisture to make it fertile; and the first consideration should be—how could this land best be irrigated from a purely engineering point of view? The general conclusion thus reached would of course have to be modified by such considerations as rainfall, quality of soil, present distribution of population, State boundaries and existing irrigation works. But the question should be looked at from the top, and not from the bottom. Little regard should be paid to the question of State or Provincial boundaries, and schemes should be thought out with the object of giving the best irrigation facilities possible on the hypothesis that the whole commanded area is under one government. Too much weight should not be given to the question of soil, although some soils give a much larger yield under irrigation than others. Experience has proved that even the sandy wastes of Rajputana and of the Thal can be made to produce fairly good crops if supplied with a sufficiency of water. Great regard should be paid to the present distribution of population. It may not be so profitable financially, but it is much more beneficial to supply the existing population with water, which increases their prosperity and security in their present homes, than to require them to migrate in large bodies to new country, although this process also should be encouraged so long as it increases the welfare both of the emigrants and of those whom they leave behind.

In order that this policy may be carried

out with justice to all concerned, the development of irrigation from the Indus and its tributaries from the Himalaya to the sea, should be placed under the control of one mind, without regard to Provincial and State boundaries. There should be a Chief Engineer for the whole Indus Valley.

In the Punjab the utilisation of the other rivers of the Province should be completed before tackling the great Sind Sagar Project for the irrigation of the Thal from the Indus. That scheme will be carried out in time, but it will not pay so well as the other canals, partly because the soil of the Thal is poor, and the silt less fertilising, and partly because it will require a great shifting of population, for which the Province is not yet ready. It is better to concentrate for the present on the other rivers, and on the more fertile land for which colonists can be readily found, and to leave the Sind Sagar Doab to be colonised by a future generation of administrators.

The policy of constructing reservoirs in the hills should be continued wherever possible.

Hitherto attention has been chiefly directed to the utilisation of the cold weather supply of the rivers. Endeavour should now be made to make greater use of the immense quantities of water which flow uselessly to the sea during the hot weather and the rainy season. This would not only enable a much larger area of hot weather crops to be grown, but would help to raise the level of the underground water-table, and bring it within reach of irrigation from wells. It is much better that these great floods of precious water should be stored underground in the Punjab than that it should be poured into the sea.

I am much impressed by the great responsibilities we are incurring in encouraging large numbers of people to migrate from their homes and settle in new villages, whose prosperity will be entirely dependent on the regular working of great canals. If, owing to any cause (whether flood or earthquake or mismanagement or local unrest or invasion from the North-West), the head-works of one of these canals fail, even temporarily, the villages depending on it will immediately, and it may be for a considerable time, lose their crops, and may even have difficulty in obtaining the water necessary for household purposes and for their cattle, and widespread misery may result. To provide against such a disaster, it is necessary that security should be maintained, that the head-works should be kept under the control of the most skilled management available, and that the villages dependent on the canal should be encouraged in every possible way to sink wells, which would enable them in case of such a calamity to draw upon the underground water-table for their drinking water and for the maturing of some small portion of their crops. The best practical means of offering such encouragement is to remit a considerable

proportion of the canal rates chargeable on crops which are matured with the aid of wells, subject to a maximum per well. Endeavour should also be made to develop irrigation from wells on a large scale by means of electricity.

In the course of my work as Settlement Commissioner and Financial Commissioner in the Punjab I became strongly convinced that the rates charged for the use of canal water were much too low, with the result that the owners and occupiers of land which happened to be commanded by a canal were given a much larger share of the benefits of canal irrigation than was their just due; and the proof of this is the very high selling value of canal-commanded land in comparison with that of uncommanded land of the same quality, possibly only a mile or two distant. This is unfair to the owners and occupiers of uncommanded land, and also to the Indian taxpayer, by the exercise of whose credit the money was obtained for the construction of the canal, and who is responsible for the payment of the interest on the loan. The rates charged for canal water, whether in the form of occupiers' rates or land revenue, should be gradually and steadily raised until they approach more nearly to the actual cash value of the water to the owner or occupier of irrigated land.

In the case of a new canal, where the people have not become accustomed to cheap water, the rates charged should, after the first few years, be much higher than the rates at present paid on most of the Punjab canals. This policy will have the further advantage of bringing a new scheme within the definition of a productive public work which would fail to reach that standard if the probable income were estimated on existing rates, and will make possible extensions of irrigation which would otherwise be condemned as financially unprofitable.

When I left India there was in some quarters a fear that developments of irrigation in the Punjab might reduce the amount of water in the Indus available for the irrigation of Sind. In a letter, which was published in *The Times Engineering Supplement* of 22nd October, 1913, I called attention to the fact that a large portion of the moisture which is precipitated over the catchment area of the Indus and its affluents sinks into the soil and is added to the vast underground water-table, which is always found in the great Punjab Plain, at varying depths below the surface, when wells are sunk, and suggested that there must be a constant flow of this underground water-table towards the sea (similar to, but slower than, the surface flow in the river-channels), and that the surplus of this underground flow must ultimately find its way back into the river-channels lower down and join the Indus at or above Sukkur, which is probably the only point at which it can find its way over the rocky barrier, which there appears above ground. I argued that if this hypothesis is correct, the supply to the

Indus at Sukkur depends not only on the surface-flow in the river-channels, but also on this unseen underground flow, and that while, by placing weirs across the tributaries of the Indus and diverting almost the whole of their winter supply on to the Punjab plains, the engineers have certainly reduced the surface discharge of the rivers as they pass through the Punjab, yet this irrigation itself, by increasing the seepage over the large area irrigated, has tended to increase the underground flow. It would follow that, even if the whole supply of the Indus and its tributaries during the winter season, at the points where these rivers enter the plains of the Punjab from the hills, were diverted from the natural river-channels over the plains of the Punjab and utilised for irrigation, the winter discharge of the Indus at Sukkur would not be seriously reduced. I am glad to see from the statistics given by Dr. Summers that, notwithstanding the increasing proportion of the winter supply of the rivers which has been withdrawn by the Punjab canals, measurements show that during the last twenty years there has been no appreciable diminution in the discharge of the Indus at Sukkur. I think, therefore, that there is no real ground for hesitating, out of regard for the interests of Sind, to make the fullest possible use of the winter discharge of the Punjab rivers for purposes of irrigation in the Punjab, and that in discussing irrigation schemes for Sind, the possibility of a serious reduction in the quantity of water available at Sukkur, owing to extensions of irrigation in the Punjab, should be left out of account.

As regards the question of irrigation in Sind, I do not know the country and I have not seen the project of 1920, which I understand has been accepted by the Secretary of State in Council, subject to its being shown that the project can be financed to completion without undue difficulty. I have read Dr. Summers's paper, in which he criticises and condemns the proposal that a barrage should be commenced at Sukkur at the same time as the Rohri canal, but I have not seen any answer to his criticism. It seems to me that he gives very strong reasons for deferring the construction of a barrage; and that, even if the Government of India are able to make out a good case for their scheme from the financial point of view, it would be wise to defer the construction of a barrage until irrigation has been considerably developed, and the need of having a barrage at all has been proved by experience. I understand that the rocky barrier through which the Indus passes at Sukkur naturally performs the principal functions of a barrage, and that it may prove possible to irrigate Sind satisfactorily without the great expense and risk of building an artificial barrage. Before venturing a final opinion on this question, I should like to know to what distance the ridge of rock which appears above the surface at Sukkur extends underground east and west of that point, and what exactly

is the danger of the Indus deserting its present course at Sukkur and forcing its way through the alluvial plain further to the east or to the west. The present generation of engineers and administrators would look very foolish in the eyes of posterity if, say fifty or a hundred years hence, the Indus deserted its present channel and left a costly barrage high and dry! I trust, therefore, that even at the present stage, the Secretary of State will appoint a Commission of experts to examine the project of 1920 before allowing the construction of a barrage to be undertaken.

19th June.

POSTSCRIPT.—I have now had an opportunity of reading Mr. Woods's valuable paper, and am confirmed in the view that, in the interests of present and future generations, the river floods should, both in the Punjab and in Sind, be stored in the vast underground reservoir, and so made available for irrigation from wells on a much larger scale than is the case at present. This should be done by a great extension of canal irrigation, especially in the hot weather, care being taken to avoid the evils of water-logging by supplying irrigation to the lands situated at a distance from the present river-channels on a more liberal scale than where the water-table is already near the surface.

I am also confirmed in the view that the construction of a barrage at Sukkur should not be proceeded with until experience has shown that it is really necessary and until further consideration has been given to the danger that such a barrage would increase the risk that the Indus may desert its present channel. I understand from Mr. Woods's paper that the Indus, even before it reaches Sukkur, flows at a level considerably higher than that of the valleys on either side. If this be so, further consideration should be given to the interesting question—Why did the Indus desert what would appear to have been its natural channel either east or west of the rocky barrier at Sukkur? and choose a course which leads it through that rocky barrier? Endeavour should be made, by borings if necessary, to ascertain what becomes of the great underground flow of water down the Indus Valley towards the sea, when it reaches the latitude of Sukkur; and, before a barrage is constructed, and even before great irrigation works, depending on the present course of the Indus, are undertaken, fuller consideration should be given to the question—What is the risk that the Indus will seek to desert its present channel, and what prospects are there that in that case the engineers of the future will be successful in keeping it to its present course at Sukkur?

28th June.

MR. FREDERICK HODGKINSON, member of the Indian Cotton Committee, 1917, in a letter regret-

ting his inability to attend the meeting, writes:—

"I am particularly interested in the projected Sukkur Barrage scheme, and sincerely hope the Government of India will proceed with the scheme without further delay. It will bring 400,000 acres of excellent cotton land under efficient cultivation, and would grow the American varieties of the longer staple suitable for Lancashire. The estimated cost of £20,000,000 would be an investment which would pay the Government many times over in the increased value of the land. One has only to compare the desolate wastes of Sind with the fruitful Punjab, to realise the benefit derived from similar land under efficient cultivation."

CORRESPONDENCE.

ELECTRIC POWER IN THE FACTORY.

MR S H. ASHWORTH, M.I.Mech.E., writes:—

I have just finished reading, with much interest, Dr. Crowley's paper on "The Use and Advantages of Electric Power in the Factory." I regret that I was not in England at the time it was read, but as I have recently been responsible for the electrification of one of the largest Indian jute mills, I give you my experiences, as they may be of interest to the Society.

The mill of which I was manager until April last is one of the three oldest concerns in Bengal, and I believe actually dates from 1864. The property consists of two mills, the original one, and a modern rope driven mill built in 1897. It is the older mill with which we are concerned at present.

This mill consisted mainly of two buildings, excluding jute go-downs and other subsidiary blocks. In one building were located the preparing and spinning departments, and in the other the weaving and finishing.

Originally each building had its own engine, but in 1891 the old engines were discarded and replaced by one 1600 h.p. engine. The transmission was entirely by gearing.

The factory contained 416 looms.

In course of time it became imperative to replace these 1600 h.p. engines, which had rendered good service for 30 years, and the problem before me was to effect the replacement with as little loss of time as possible.

The only course open appeared to be to electrify the place, and this was decided on.

A power house was constructed close by the mill, and Parsons' turbo-alternators with B.T.H. motors and switch gear were installed. Voltage 500, frequency 50~.

As it was out of the question to couple the motors direct to the shafts which were mostly slow speed, varying from 100 to 220 R.P.M., I decided, after careful investigation of the

various methods of transmission, to adopt the chain drive, and place the motors on the roof of the mill, which was strengthened where necessary to carry the extra load.

Only three sizes of motors were used, viz., 125, 100 and 60 h.p. These small units were adopted in order to avoid very heavy chains.

The motors were disposed as follows:—

Batching preparing 7 motors	125 h.p.	875 h.p.
Spinning and warp winding 3 motors		
100 h.p.	300 h.p.	
and half of finishing 3 motors	60 h.p.	180 h.p.
Yarn dressing and cop winding 1 motor	60 h.p.	
Looms, 4 motors	60 h.p.	240 h.p.
Finishing and sewing, 1 motor	100 h.p.	
h.p.	100 h.p.	
Total h.p.	1755 h.p.	

The job took a considerable time to complete, as the bulk of the work of connecting up had to be done at the week ends. It was, however, carried out without stopping the mill for an hour.

The increase in production due to the electrification of the looms and the modernising of the mill generally, has been truly surprising.

In the old days we used to consider anything from 40 to 45 tons per day as a very fine production indeed, but during the year just past, the production has varied from 47 to 57 tons for 432 looms; the smaller tonnage being entirely due to the lighter fabrics being made. As a matter of fact, the yardage was practically constant throughout the year.

This represents an increase of about 20 per cent. per loom, of which I consider 15 per cent. to be entirely due to the more even running of the looms.

I have also been intimately connected with the building of two new mills near Calcutta since the war, one of which was able to purchase power, but the other had to generate its own power, and it was finally decided to drive this mill by geared turbines and rope transmission.

The electrically driven mill was arranged with a cable and control gallery on the roof along the centre of the mill. The motors were direct coupled to the shafts, except in the weaving shed, where chain transmission was adopted. The motors are carried on platforms, or suspended from the roof in the case of the small motors.

No individual drive was adopted, except for the pumps, although I am in favour of such a drive for certain machines.

This mill was not completed when I left India, but I understand that it is now working quite satisfactorily.

When drawing up the plans for this new electrically-driven mill, I was impressed with the fact that we could not get away from the steam boiler. We had to allow over a lac of rupees, i.e., nearly £7,000, for boilers to generate steam and heat required in the manufacturing

processes of batching, yarn dressing and calendering. In addition to the heavy capital expenditure, this boiler plant takes up valuable space.

I can well imagine that this fact would turn the scale in favour of a steam turbine or reciprocating engine drive in many cases.

It seems to me that electrical engineers might set to work to eliminate the steam plant altogether in jute mills with advantage.

ESSENTIAL OIL AND PERFUME INDUSTRY IN ITALY.

The Italo-English mint is cultivated to the extent of about 600 hectares (1,482 acres) in Piedmont. Calabria and Sicily furnish the "esperidee" (lemon, bergamot, sweet and bitter orange, mandarin, citron, etc.), the peel of which furnishes high-grade essential oils, constituting a leading industry of that region, which is only slightly less important than the production of citrate of lime and citric acid, obtained from lemon juice. Lavender, herbs, and plants are plentiful in the western Alps; resinous plants are found in Alto Adige, in north-eastern Italy; rosemary, thyme, juniper, absinthe, and many other herbs and plants abound in Sardinia; aniseed and fennel are raised in Romagna; and the rose, carnation, violet, and other flowers are grown along the Ligurian Riviera. These essences are not only indispensable in the preparation of perfumes, liqueurs, confectionery, etc., but are largely used in pharmaceutical preparations.

One firm, says the United States Consul at Genoa, has succeeded in producing from the Brunner rose of the Riviera, an essence of which 20 kilos was sold in 1919, the first year of its appearance on the market. In order to obtain 1 kilo of this oil about 5,500 kilos of petals, with an approximate value of 4,300 lire per kilo, are used.

The Italian Government, by the decree of November 17th, 1918, exempts for a period of 10 years from the land tax and income tax, lands which are given over to the cultivation of flowers, plants, and aromatic herbs for distillation. This exemption will also be extended for a period of five years to factories which produce essential oils.

LANGUAGE OF TECHNICAL BOOKS USED IN BRAZIL.—The monthly statistics for April of books consulted in the library of the Polytechnic School in Rio de Janeiro are of interest as showing the relative use of scientific works according to language. The figures are as follows: French, 244; Portuguese, 56; English, 20; German, 2; Italian, 2; and Spanish, 2. Though covering only one month, these figures, in the opinion of the United States Commercial Attaché at Rio de Janeiro, are undoubtedly representative as showing the predominance of French books and French translations of other foreign works in this class of books.

PROCEEDINGS OF THE SOCIETY.

DOMINIONS AND COLONIES SECTION.

FRIDAY, JUNE 9TH, 1922.

THE RIGHT HON. SIR FREDERICK D. LUGARD, G.C.M.G., C.B., D.S.O., in the Chair.

THE CHAIRMAN said that since Sir Humphrey Leggett had previously read a paper before the Society, he needed no introduction, and his long connection with East Africa had made him widely known as one of the greatest authorities on trade and commercial subjects in that region. He belonged to the distinguished Corps of the Royal Engineers, which had provided the Empire with so many of her most distinguished administrators, prominent both in peace and war. After leaving Woolwich, Sir Humphrey specialised in railway work, and went to South Africa in 1899, remaining there for five years on the staffs of Lord Kitchener, Lord Milner and Lord Selborne. His knowledge of the Dutch language and his conspicuous tact qualified him for the difficult task of Director of the Burgher Land Settlements.

After leaving South Africa he was deputed by Mr. Alfred Lyttelton, the then Secretary of State for the Colonies, to go to East Africa to report on the developments by which the railway there could be made a paying concern. Since that time he had been continuously in touch with the country. In 1907 he returned there to put into operation the schemes he had proposed and for that purpose he founded in 1907, the British East Africa Corporation, being seconded by the War Office. He became so interested in the work that he resigned the Service in 1911.

During the late War he was employed in very confidential duties in England as an agent of the War Office, in close collaboration with his friend Lord Kitchener. His work largely consisted of facilitating the operations of the Belgians in the East African campaign, and for that difficult and delicate employment he was knighted and also received a high Belgian decoration. He visited East Africa again in 1920, and was then able to see the remarkable difference which the change from German to

British control had produced in the Tanganyika territory. During his previous visits to the country he had often been able to go to German East Africa, and was on friendly terms with its administrators.

The paper read was :—

THE TANGANYIKA TERRITORY.

By MAJOR SIR EDWARD HUMPHREY MANISTY LEGGETT, D.S.O., R.E.

In expressing my appreciation of the invitation accorded me by the famous old Royal Society of Arts, Commerce and Manufactures, to address you to-day on so interesting and important subject as the Tanganyika Territory, may I say how proud I am to find myself, if only for this afternoon under the orders of our very distinguished Chairman, Sir Frederick Lugard? Every Englishman who has worked in any capacity in tropical Africa as civilian official, soldier, missionary, or trader, will bear me out when I say that for a quarter of a century, or longer, it has been the cherished ambition of each one of us to find himself in some capacity serving under Sir Frederick. What Mr. Chamberlain was, and for all time will figure in our Empire's history, the Apostle of the British Empire Overseas, that is, and for all time will be, the place of Sir Frederick Lugard in relation to tropical Africa. When he, then Captain Lugard, began his life's work in Africa, the problems, potentialities, responsibilities and rewards that the Dark Continent held in store were either unknown or were the sport of political ambitions among the nations, of impractical idealism on one hand or of ruthless materialism on the other. Principle and practice were alike undefined. What that quarter-century has evolved, a whole code and creed of practice and of ideal, is set out in clearest form in our Chairman's own recently-published book "The Dual Mandate," an exposition of the mutuality which exists between European civilisation and the backward regions of the African

Continent. He shows on the one hand, the vital need which civilisation has of the tropics, with the duty to develop their vast potentialities to the utmost, and, on the other hand, the lesson that he who takes must give, and give of his best. The older civilisations cannot merely take and hope to go on taking, but they must carry the torch of their own culture and progress, and in every act of administration and commerce, and even of missionary effort, must keep in mind that the world is made for all its inhabitants, not for this or that colour, or section, or nation only.

These are truisms to-day. I must almost apologise for repeating the obvious—but 25 or 30 years ago, and more recently than that, the collective consciousness of the European nations had not envisaged the problem, much less agreed upon its solution. But now the work of Sir Frederick Lugard, and of those under him, has so taken root that our present generation may not always recall that the tree is not a hoary oak, but is still a growing plant, and that every one of us has his bit to do in helping that it never becomes stunted nor deformed.

To the vast areas over which this great tree—the British system in tropical Africa—has been established, is now added a fresh country, ex-German East Africa, the size of France and Germany rolled into one. Up to 1914 that country was administered, developed, exploited, on a system differing profoundly from our own. Efficiency, discipline, material progress, were in it almost painfully present to the most superficial observer, yet even the Germans themselves were beginning to doubt whether all was really well. Thinking men among them were uneasy, but changes such as the case would demand must come from the heart, as well as from the head. National temperaments are not readily readjusted. It required the upheaval in the old world of so-called civilised peoples to bring about the change of circumstances that will so profoundly affect this great portion of tropical Africa.

I must attempt, therefore, to summarise to you what the Germans, their Government and their people, had done with and in this greatest colonial possession, from the time of its acquisition by them up to 1914.

Their East African dominion began officially in 1885, in accordance with the sanctions of the Berlin Conference of that year, at which were represented all the European nations having territorial and

other claims in the tropical belt of Africa. You will remember how for some years previously, those regions had been the field for a great game of individual grab. Adventurers of various descriptions, respectable and otherwise, from Stanley to Carl Peters, had entered tropical Africa from East and West, making treaties with native chiefs, slave raiders, and almost anybody of local influence, by virtue of which documents of all sorts of rights, territorial, commercial and otherwise, were given just so much reality as it might suit their respective Home Governments to recognise and to support in the international diplomatic field.

None seized its opportunity with more avidity than Germany. The "scramble for Africa," as it was called, led naturally to overlapping of claims, partition of tribes, conflict of economic interests. Unsound frontiers, impossible lines of transport access, and the like, were inevitable. Something had to be done, if disagreements were not to breed warfare in Europe, as well as bloodshed in Africa. Diplomacy was equal to the occasion, at least for the moment, and invented the "sphere of influence." Thus were born in 1885 the Congo Free State, German East Africa, Nyassaland, the Italian Benadir Colony, and the chartered territories of the Imperial British East Africa Company (afterwards the B.E.A. and Uganda Protectorates). The Sultan of Zanzibar continued his independent sovereignty of his island kingdom, along with his more shadowy territorial rights along the mainland coast from Cape Delgado on the south to Guardafui in the north. These mainland rights he had offered to Sir John Kirk, who accepted them in trust for the British sphere of influence. The inland limits of the Sultan's dominions were vague in the extreme. Lord Kitchener, then Major Kitchener, was sent in 1886 to unravel them if he could. The knot could not be untied, so he recommended a simple way to cut it, viz., to assume a ten mile strip along the coast line as belonging to the Sultan and all inland of that line to fall to the "sphere of influence" of the respective European powers. Exactly a quarter of century later, in 1911, he visited Mombasa on perhaps the only holiday of his life, and there I had the privilege of hearing him discuss over again with the venerable Sheikh Salim bin Khalfan, his friend of 1886, the outcome of that rough and ready settlement, and the benefits on which the two

were cordially agreed, that had flowed from it.

From 1885 to 1890, the European powers were busily occupying and exploring their spheres of influence, native warfare was almost continuous, and boundary negotiations were set on foot. In 1890 the Sultan's mainland dominions were partitioned. Germany purchased outright for £200,000 the ten mile strip along her 300 miles of coast. Italy did the same. England entered into a perpetual lease for the strip in her zone, which included the Port of Mombasa, on a rental of £17,000 per annum, which is paid punctually to this day to the

Sultan's Treasury. Coupled with these arrangements, a composite treaty as between the various European Powers themselves provided for the open door, and equal rights to the nationals of all Powers, in matters of shipping, customs duties and other trade facilities. Within a few years the commercial population of the British ports was 50% German. In the German ports and towns not an Englishman, indeed, hardly any European save Germans themselves, ever became established. There was no law against them, but the non-German simply found an unclimbable wall of obstruction. No British ship called at the German

ports, no British planter or farmer could get the title deeds to his land quite in order. There was no boycott. It just happened so.

Thus, by 1890, German East Africa had its boundaries, its own place in the sun, and started on a career which, until 1905, at any rate, afforded more scope to its military than to its civilian administrators. At an early stage the home people of Germany undoubtedly looked to their colony (as they invariably called it, in rather significant contradistinction to the British use of the term Protectorate for our own adjacent territories) as a field for the expansion overseas of their surplus home population. Britain had founded great overseas communities—Canada, Australia, New Zealand. Rhodes was acquiring more ‘homes’ for England by annexing Rhodesia. Why should not Germany found colonies of the same type to grow into strong outposts of her Empire? The fact of a large resident native population was not overlooked—it could not be—but it could be used. Colonists need labour. So from an early stage the grant of lands to German planters and planting companies became a prominent feature of their system, though from reasons of prudence and economy of administration, these were confined practically to regions within fairly close reach of the coast. It is beyond doubt that the serious native unrest that prevailed in nearly every district, culminating in the rebellion of 1905, was due in large measure to the disregard of native land rights. In the quelling of the 1905 rebellion more than 100,000 natives, men, women and children, were killed or died from the starvation that followed the military operations, conducted as these were with ruthless method and completed by the deliberate destruction of all food supply throughout several provinces. The rebellion itself included the murders of many Europeans, officials, missionaries and traders, and for some years afterwards the districts concerned were ‘*verboden*’ to missionaries and traders, and were virtually unadministered and unvisited, except by military patrols. These events, as it is perhaps interesting to mention, synchronised with the last of the minor native campaigns in British East Africa, the so-called Nandi War, when the Nandi tribe gave trouble by raiding the cattle of its neighbour, the Kavirondo. Not one white man was even injured, the casualties among the British troops amounted

to three men, and to the ‘enemy’ not much more. I was at the headquarters of the British force at Muhoroni on the day when the grand attack was expected to take place. The ‘enemy’ were massed in their position, and, no doubt, some bloodshed would have occurred. Over the wire came an order from the Secretary of State, Mr. Alfred Lyttelton, to the effect that if the Nandi would promise to keep to their side of a certain line, and the Kavirondo on their side of a parallel line 10 miles away, the war should be ‘called off.’ They did, and not a shot has been fired there since. Less than a year later I walked through the Nandi country with an agricultural inspector and our personal boys, with no other weapon than a shot gun to shoot guinea fowl.

‘Frightfulness,’ however, had ended native rebellion in German East. The country was divided into administrative areas, which by 1914 totalled 24, of which 19 were civil districts, two still remained under military Government (Mahenge and Iringa), while three, being of an outlying and special nature, were given the status of residencies (Ruanda, Urundi and Bukoba). These latter contained a specially dense population, nearly one half of the total of the whole country ($3\frac{1}{2}$ out of $7\frac{1}{2}$ millions) and decentralisation in their case was an obvious necessity.

The method of occupation and pacification had completely destroyed whatever existed of tribal organisation. ‘*Divide et impera*’ was the maxim. For the detailed work of administration the Germans relied upon a system differing profoundly from that which the British system, both in East and West Africa, has invariably adopted whenever the conditions for it were found to exist, namely, the administration of tribal communities through their own chiefs, and, indeed, on the basis of their own ancient laws and customs so far as those be not incompatible with elementary justice and order. The German Government found, on the coast at any rate, the system set up by the Sultans of Zanzibar—absentee lords, so to speak—whereby each district or sub-district was administered by an Arab or Swahali, known as the *Akida*, a military title not unsuitable to the representative of an alien master interested only in tax collection and the slave trade. These alien officials, working upon an Oriental method, with material inducement to

efficiency, became suitable agents for the German power. Under the German Commissioners of districts, the Akida exercised certain magisterial jurisdiction over the natives, including the power of inflicting corporal punishment, and were even responsible for collection of taxes. A native police force, considerable in numbers and of marked efficiency and loyalty (as the War proved in 1914-1918), assisted the District Commissioner and his Akida or Akidas. That the system was cheap and efficient for the rather short sighted purpose in view, is undeniable. But it carried within it the seeds of future trouble, and was incapable of, if not indeed actively opposed to, the furtherance of native progress. Readers of Gibbon's "Decline and Fall of the Roman Empire," will find parallels almost exact in the administrative systems, based on military power, by which Rome held sway over her outlying possessions in North Africa, which, with her fall, relapsed instantly into savagery, as if the great central power of the Cæsars and all the arts and civilisation of the Augustan age had never been.

Under this system, however, labour was, with increasing difficulty, provided for the plantation system that had been set up. The land grants had been made chiefly in three districts, the Usambara Province, including the fertile slopes of Kilimanjaro, the central district between Ruvu and Morogoro, and, more recently, in the Lindi district at the extreme south of the country around the ports at the mouths of the Lukeledi and Rovuma rivers. By 1912 it was becoming clear that to alienate further lands would result in serious unrest, if not actual rebellion, and further land grants to Europeans practically ceased. Even by then it had become evident that the demand for labour in the settled districts named was far in excess of local supply, and the dangers and difficulties of maintaining sufficiency of recruits, from the not very populous hinterland, were becoming patent, even, indeed, if a sufficient reservoir of labour existed at all in those regions. The entire native population was only $7\frac{1}{2}$ millions. Of this, about $3\frac{1}{2}$ millions lived in Urundi and Ruanda far beyond practicable distance. The remaining four millions in the main body of the country would include, on the usual average, 300,000 to 400,000 only of what may be called labour age. The official statistics of the German

Government for 1921, showed that 94,000 native males were then regularly engaged on plantations and mining, 25,000 on railways, harbours, and other Government service (exclusive of military and police), 20,000 in domestic and commercial work, and at mission stations, 15,000 on caravan work, 6,000 police and military, and 12,000 miscellaneous, totalling about 175,000 males in employ at any one time. Allowing for absences and spells of rest, or return to their tribes between periods of labour, such a force continually engaged would take up 75% of the male population of suitable age, even reckoning in the population of the most remote districts, but exclusive of Ruanda and Urundi. The remaining males of labour age, with the old men and boys, and the women, would be none too many to maintain the food supply of the country, and in this connection it is worth noting that the plantation wage and labour system did not include the issue of posho, or rations, which the labourers were expected to buy for themselves, thus pre-supposing a supply from the non-wage labour population.

With these labour resources, the Germans, by 1912, had established certain main plantation industries of high technical efficiency. The latest official figures stated the areas under certain permanent crops to be as follows:—

Sisal Hemp	61,877 acres
Coffee	12,000 acres
Kapok	5,800 acres
Rubber	112,000 acres

The production, as measured by the 1913 exports, was as follows:—

Sisal Hemp	21,000 tons
Coffee	600 tons
Rubber	1,000 tons
Kapok	60 tons

By 1913 the rubber export was already falling, due to the high cost of production from the small yielding Ceara tree, and that industry in East Africa would probably have been dead to-day even had the War not occurred. Had no interruption occurred the sisal output would by now have, in normal course, probably reached 60,000 tons per annum, for very large areas, employing in the planting up much of the labour mentioned, had not in 1914 reached the production stage. Coffee, for the same reason, would probably have reached 3,000 tons, and has, perhaps, suffered less than sisal from the long spell of suspended

activity. But enough has been said to shew that the limits of development of the Colony, on purely plantation basis, were in sight, and that further progress on those lines would have had to await the natural growth of population, coupled with labour saving methods. On the other hand, certain risks were apparent from the fact of an increasing discontent among the natives with the system to which they were being subordinated.

From about the year 1910 appears to date a consciousness on the part of the authorities that it would be necessary to supplement the State revenue by the stimulation of native production of exportable economic crops, the sale of which would increase the native buying power, and that in turn would add to the customs and railway revenues, besides providing outlet for goods from home and profitable enterprise for traders. Until then cotton, which I have not yet mentioned, had been also regarded chiefly as a plantation crop, and under the guidance and with the help of the *Koloniale Wirtschaftliche Komitee* (the Colonial Economic Society) fair progress had been made, mainly in the coast regions, to a total of some 5,000 to 6,000 bales per annum. German officials visited Uganda, where the crop already exceeded 25,000 bales per annum, grown entirely by natives for their own account, to be sold by them to the highest bidder. The result of this was that a start was made on what may be called Uganda lines, or, indeed, British lines, with the natives in the districts at the south end of Lake Victoria, who by 1914 were producing on the Uganda system at the rate of 3,000 or more bales per annum. The suitability of the coast, especially in the Rufigi delta, the Lindi and Songea districts, and in the central district near Morogoro and Kilossa, for production on this system, was probably not overlooked, but the vested plantation interests and the demand for plantation labour was, no doubt, the reason why native crop cotton growing was not encouraged in those regions. By this system, men, women and children, working their own tribal or communal lands for their own account, it is now reliably estimated, by British experts since the war, that the country has a cotton capacity within a very few years of anything up to 100,000 bales per annum, without interfering with the food supply also grown by themselves for their own consumption,

nor with the plantation interests to be resumed on a carefully limited scale.

In addition to cotton by native non-wage labour, the German authorities were undoubtedly eager to increase the production, on the non-wage labour system, of groundnuts, for which the Lake districts are specially suitable. Not only is this product of considerable export value, but it also provides a valuable alternative local food supply. It is only fair to say that their efforts in this direction were checked and limited by the capacity of the British Lake steamers and Uganda railway—the only means of transit from Lake Victoria to the coast—to carry the output. Some 4,000 tons per annum was all that the British railway could carry at that time. The potentiality of the districts is undoubtedly many times that figure.

To sum up, in the last year for which statistics are available before the war, the exports of German East Africa totalled a value of £1,570,915, derived as follows:—

	£
From European plantations ..	729,650
From products partly European, partly native	278,800
From wild products (wax, copal, etc.)	107,000
From semi-wild products (hides and skins)	216,250
From purely native produce ..	102,000

In return the country imported in the same year almost exactly 2½ million £ sterling of goods, made up of half million pound worth of railway and building material and specie, £800,000 worth of cotton goods (almost entirely for native use), and 1½ million pounds worth of other articles, of which nearly £400,000 was divided equally between rice for native food and other foodstuffs.

To close our summary of this period, let me add that at the outbreak of the Great War the European population was approximately 5,500. The official figures of January 1st, 1913, gave the male population as 3,536, of which Government officials were 551, missionaries 498, military 186, planters and farmers 882, engineers and mechanics no less than 705 (a very interesting figure), while 523 were classified as merchants and traders, with 189 miscellaneous unclassified males to represent the professional and leisured classes. These figures, it should be noted, included Greeks to a total of about 1,200, largely employed as mechanics,

plantation overseers, and on railway work. The Indian population was estimated at 9,000, and was increasing rather rapidly, chiefly as traders in the interior, following up the efforts to stimulate native grown products, for which they provided the market, for without these retail traders, the native products would be in danger of finding no certain outlets.

The railway system of the country was conceived on lines which appear to disclose a wide strategical, as well as a local economic policy. The Usambara line, 220 miles in length, with ocean terminus at the port of Tanga, was commenced in 1893, with projected terminus on the slopes of Kilimanjaro, a region at that date not finally clear of frontier dispute. The line was opened to Mombo in 1905, 80 miles from the port, and the extension to the present terminus at New Moschi, 220 miles from the coast, was opened in 1912. The working of the line was leased to its construction contractors, and by 1914 had not reached a profit-making stage, due, no doubt, to the unproductive character of the zone lying between Mombo and the fertile Kilimanjaro plantation area. This latter region is now in direct rail communication with the British port of Kilindini, over the link line built by our forces during the war to connect with the British main line at Voi, and the natural outlet of the Kilimanjaro region in the future would seem to be through Kilindini. The German Central Railway was begun only in 1905, starting from Dar Es Salaam, reaching Morogoro in 1908, Tabora in 1912 and Lake Tanganyika in 1914, a total length of 780 miles. In 1914 a fine cargo steamer was launched on Lake Tanganyika. The system obviously ranks as one of the main arterial routes of Africa, serving the extensive coast line of that Lake, providing the most direct communication with vast areas of the Eastern Congo. In 1912 the Consulting Railway Engineer of the Berlin Colonial Office described to me Tabora as the Clapham Junction of East Central Africa. He forecasted branch lines from Tabora to Mwanza on Lake Victoria, with a fork running north west into Urundi and Ruanda up to the southern frontier of Uganda. These branches were, in fact, actually approved in 1913, and work was started, the formation being completed for about 100 miles, with 30 to 40 miles of permanent way actually laid when war broke out. He forecasted

also an important branch from Tabora to the south west, to connect with Rhodesian territory in the neighbourhood of Abercorn, with intent to tap the Southern Congo and North East Rhodesian traffic. The out-flanking of the Nyassaland Lake system was clearly in the ultimate objective. The final achievement of these plans is now in other hands, and we may perhaps express the hope that, under British auspices, they will not be unduly delayed. As a mere illustration of the annihilation of time and distance that these schemes will effect would be the shortening of the present journey from London to Abercorn, say, six weeks via South Africa, to 23 or 24 days via Dar Es Salaam and Tabora.

Somewhat strangely perhaps, little or nothing was done to improve the natural harbours at the two ocean termini, Tanga and Dar Es Salaam. At both ports deep water berthing facilities, although practicable at quite moderate capital cost, were totally neglected. Messrs. Hansing and Co., the agents of the heavily subsidised German East Africa Steamship Line, held a virtual monopoly of lighterage, and landed all inwards cargo at a charge of 7 marks per ton at Tanga, 5 marks at Dar Es Salaam. Export cargo could be and was conveyed to ships by dhows and other privately owned craft, but in 1913 the Government imposed a wharfage fee which, from 1914, was to be collected for Government behalf by Messrs. Hansing, coupled with a remarkable provision that if the services of that firm were not employed in the landing or shipping, a surcharge on the wharfage fee was to be levied. The result could only have been to grant to Messrs. Hansing a virtual monopoly of the port working. All this, of course, is now a matter of history only, but it is permissible to express the hope that the British authorities will allow no similar vested interests to grow up in these important ports to interpose a grasping hand between ship and shore, and thus to levy toll on every import and every export. We may note with interest the recent news that His Excellency the Governor of Tanganyika has directed an enquiry to be undertaken into the cost and other details of providing a deep water wharf alongside which ocean steamers can load and discharge their cargoes.

I will not attempt to describe the War operations which commenced simultaneously with the Great War in Europe. Heroism,

endurance and a splendid loyalty to their salt, were features on both sides, and on both sides it may be said that the War was cleanly fought. But two special points are of interest in connection with our general subject. The German system of semi-military administration enabled them in a very short time to put about 10,000 trained native troops into the field, by the process of calling up ex-soldiers and ex-policemen, who had served their time and passed back to the civilian population. The exceptional number of European officers and non-commissioned officers retained with the regular troops during peace, amounting to no less than 10% of the rank and file peace establishment, provided for the officer-ing of this quadrupled army, and undoubtedly took us by surprise. A further comment that may be made is that until 1914 it was almost generally expected among white men throughout Africa that come what might in Europe, the powers in Africa would not use native troops against each other, but would bide by the result of War in Europe itself.

British civil administration commenced in the Northern portion of German East Africa in March, 1916. Mr., now Sir Horace Byatt, was appointed Administrator of the captured areas, working in co-operation with the Commander in Chief, General Smuts. In March, 1918, the jurisdiction of the Administrator was extended to districts south of the Central Railway. The country remained under martial law, the Commander in Chief being supreme, and it was not until January, 1919, that a Royal Commission was issued appointing Sir Horace Byatt as the supreme authority. Under the Versailles Treaty of 1919, Germany renounced in favour of the principal Allied and associated powers, all rights to her overseas possessions, including German East Africa, and this was followed by the decision of the Allied powers to confer upon Great Britain a Mandate to administer what had now become ex-German East Africa, in accordance with certain principles laid down by the covenant of the League of Nations.

It will be remembered that the Belgians proved themselves good and loyal Allies in the East African Campaign. Their operations taking place from the north and east, it came about that they found themselves in military occupation of the Eastern portion of the country from Lake

Tanganyika as far as Tabora, besides the North Western districts of Ruanda and Urundi. In the settlement of Mandates, it was decided that Ruanda and Urundi should be placed under Belgian Mandate, and these important areas are therefore now finally dissociated from the Tanganyika Territory, and are, as a matter of fact, being administered under the Governor General of the Belgian Congo. The Belgian Authorities continued to administer the zone between Tabora and Lake Victoria for some time after the Peace, but this area has been gradually handed over, and is now entirely under British Administration.

It would take an international lawyer, which I am not, to define to you the precise juridical status of a mandatory country. Just as diplomacy at the Berlin Conference of 1885 invented Spheres of Influence to meet a situation that was without precedent, so did the ingenuity of man overcome the obvious difficulties that were seen to lie in the way of out and out annexation of this or that German possession by this or that of the victorious allies. The principle underlying the Mandate system is, however, clear. It is laid down that the country under mandate shall be so administered that the Mandatory Power shall promote to the utmost the material and moral well-being and social progress of the inhabitants, that there be ensured to all Nationals of States, members of the League of Nations, equality of opportunity in the economic, commercial and industrial spheres, with freedom of transit and navigation, and in short, that the potentialities of the Mandate country shall not be monopolised to the benefit of any single power. Subject to these conditions, which, indeed, have been inherent in the British system in the purely British owned Territories of Africa, there appears nothing material to distinguish the position of a mandatory administering power from that of an out and out sovereign. The draft of the Mandate for ex-German East Africa has been published and includes the points I have just mentioned. It is understood that it has still to come before the Council of the League of Nations for final approval. A curious problem undoubtedly exists, for which diplomacy appears already to have found a solution. America, though a signatory of the Versailles Treaty, never ratified that Treaty, but concluded a separate peace with Germany. The renunciation of her Colonies to the principal

allied and associated powers included America, in the first instance, among the latter, and had she ratified the treaty, she would have become a party to the mandate. Being outside the treaty, America is no longer one of the powers on whose authority the Mandate has been, or will be, definitely based. This difficulty seems to have been overcome in the case of Palestine by means of a separate Treaty between America, herself and Great Britain, the mandatory power, and doubtless a similar instrument will be necessary in the case of ex-German East Africa, and it can, no doubt, be assumed that such a Treaty would afford to American Nationals the same complete freedom of opportunity that is to be enjoyed in the country by the Nationals of the other Treaty powers.

Six months after the ratification of the Peace Treaty, and the coming into effect, *de facto*, if not *de jure*, of the Mandate, a British Order in Council was promulgated constituting the office of Governor and Commander in Chief of the Tanganyika Territory, which thus became henceforward the official name of the country, and Sir Horace Byatt, K.C.M.G., was appointed to that position.

Much spade work had been done in examining the condition of the country, more particularly in providing by means of district political officers for the control and administration of the native population. The German staff had been swept away, but the Arab or Swahili Akida, already explained to you as wielding so much of the detailed administrative power under the German District Commissioners, were in many cases still on the spot. Their local knowledge was, of course, invaluable, and although some, perhaps, might not exactly welcome a change of system under which their individual powers were bound to suffer material check, as a rule they accepted the situation and were glad to transfer their allegiance. It is obvious that the call upon tact, energy and insight into native character, required of the British District Political Officers by the abnormal conditions that existed, must have been immense, and the fact that the change over from German to British Government throughout so vast a country, after all the cataclysms of war, was accomplished without serious trouble among the natives, speaks volumes for the governing capacity of the Englishmen concerned. Much even now obviously

remains to be done. Tribal organisation, where possible, is the obvious goal, and as a step towards this, Arab or Swahili alien Akida will, no doubt, be gradually replaced by chiefs and headmen emerging from the body of each tribe or community. Native law and customs will also emerge, differing doubtless in the various parts of the country, but adopted where suitable to the various sections of the native population, so far as compatible with justice and order. When once cohesion within a community, be it village, group of villages, or tribe, has taken root, the problems of administration will become greatly simplified, and with them, the success of economic development, technical education, hygienic measures, and the like, will rapidly advance. Progress in all these directions is already clearly visible.

The fate of the lands that had been allotted by the old German Colonial Government to Germans and other Europeans, presented an immediate problem, which was much complicated by the destruction or disappearance of title deeds and other records during the War. Under the Reparation and Enemy Debt Clauses of the Versailles Treaty, all private property of enemy Nationals in the ex-German territories, became ceded to the Allies, compensation to their original enemy owners to be made good by the German Government. The first obvious difficulty was to ascertain the ownership of each plantation or other land that had been in European occupation. Some were the subject of claims by Greeks, Swiss and other non ex-enemy people. As an ex-enemy title to any plantation area, trading site, building or other real property becomes finally proved, after exhaustive examination and test, and due notice of appeal allowed, the property is proclaimed in the Government Gazette as falling within the disposal of the Custodian of Enemy Property, acting under the administration of the Mandatory power. From time to time, lists of these properties are being advertised for sale, and they may be purchased from the Custodian at open auction, or by private treaty, by any except ex-enemy Nationals. The buyer, moreover, is called upon to enter into an undertaking that his purchase is neither directly nor indirectly for behalf of an ex-enemy. By this procedure, town properties at the chief ports and other centres, have already largely passed into the hands of British and Allied Nationals, and the similar

disposal of plantation areas has been proceeding during the past year. Some complaint by would-be buyers has made itself heard as to the comparative slowness with which the operation is being carried out, but seeing that the Mandatory power, i.e., the British Empire, is guaranteeing to the buyer an indefeasible title to the property, it appears to be only commonsense that no such sale should take place, or title be granted, until the original enemy ownership has been established by the utmost proof and test. The Torrens System of Land Registration has been, or is being, set up in the Territory, and buyers of these lands will thus enjoy the facility of registration, with all that it implies, in the security of occupation and ability to sell, lease or otherwise dispose of their interests for their own behalf, with the minimum of legal expense.

Before leaving this subject of European land holding, I venture to suggest that the difficulties that the Germans were beginning to apprehend in the matter of labour supply, should not be overlooked. If it be true that more land was granted before the War than there was labour, on a voluntary system, adequate to develop, it would seem in the highest degree unlikely that the same total area could safely be transferred to Europeans at the present moment, when the country has not recovered from the disturbance of War. The plantations, moreover, now require exceptionally large labour gangs for their restoration after years of jungle growth. It will be surely disastrous to the buyers themselves, if unduly large land holdings are purchased in the hope of sufficient labour being forthcoming, and then to find their operations checked, and their capital rendered partly idle by shortage of man power. Anything approaching the compulsory or semi-compulsory methods adopted by the Germans must always now remain out of the question, but it may not be too much to suggest that a moral responsibility is likely to be argued as attaching to the Government, if by selling these lands and thus inviting European occupation on too large a scale, a labour shortage should make itself felt in the future.

Side by side with this matter of land disposal and the slow but sure restoration of the valuable planting industries, more particularly in sisal and coffee, the Tanganyika Government has been giving its attention to the establishment of stable

crop production by the natives on their own land and for their own account. More particularly, attention has been paid to cotton and ground nuts, while not neglecting articles of local food consumption, such as rice, maize and millet. The world depression of the past two years has been a heavy handicap in these matters. Cotton, when grown, could not be sure of a market, and the same could be said of the collecting of hides and other natural products of the country. What has been proved, however, is the extreme readiness of the natives in practically every region to accept the advice of the district officers and to cultivate with a real energy. Seed has been asked for in increasing quantities, and it is on record that cattle owning tribes even show such enlightenment to their own interests as to request the Government to supply high grade bulls by which to improve their herds.

The Germans in later years had been devoting increasing attention to the education of the native, chiefly on the technical side, probably not without recognition of the fact that until a skilled class could be created among the indigenous population, the influx of orientals for clerical and subordinate technical work could hardly be avoided. Considerable headway has been made by the British Government and the Missionary Societies, in restoring the schools, and the figures of attendance are gratifying. Before the war, no less than 1,832 schools were being conducted by the Missionary Societies, and 99 by the German Government, and the number of children on the registers of attendance exceeded 100,000. While quite possibly some rather forceful persuasion was at work, the figures are so large as to illustrate the keenness of the African native to take advantage of the opportunity given him by schools to advance his future prospects.

Among the more material problems of restoration, none could be more important than that of restoring the efficiency of the railway system, which suffered serious damage during the war, both to track and to rolling stock. In all these matters much has been done, but much remains to do. Traffic is, at any rate, being regularly forwarded over all the lines of railway, as mentioned earlier in this paper, but unless the carrying capacity be considerably increased by the further restorations still to be done, and by the provision of further rolling stock, any material increase in the

production of the inland districts would meet with serious check by the difficulty and delay in finding an outlet to the coast. In the same connection, I have already mentioned the need for improved harbour equipment and deep water berthage.

Before closing this review—necessarily inadequate for so big a subject—it is worth while to notice the generous financial provision which has been made, and further provision forecasted by the Imperial Government towards the restoration of this derelict country. I believe I am right in saying that for 1920 the British taxpayer provided £330,000, for 1921 something like £800,000, and that in the Imperial Colonial Office estimates for the current financial year another sum exceeding three quarters of a million pounds is asked for from the British taxpayer. These sums, so far as I know, are an out and out grant by the United Kingdom, to what we may term its adopted orphan child. No interest, no tribute, no monopolistic rights from the fructification of these immense sums are asked for, or made a condition of the grants. If ours is a country of shopkeepers, at least we may urge, with pride, that the shopkeeper is not afraid to put his hand in his pocket when it is a case of "noblesse oblige." The taxation of the natives and the trade taxes upon Europeans in the territory remain at the low pre-war level at which they were left by the Germans in 1914, the deficit unavoidable in the administration of the country being met from the grants of aid that I have mentioned.

In this paper I have not attempted to describe to you the physical and other features of the country—rainfall and other details—for I have felt that at this somewhat early stage in its history under British administration the great and salient feature is that of the implanting of the British system of native and land administration upon a country hitherto governed on other lines. Side by side with this general matter, I have tried to indicate the main directions in which economic development is likely to proceed in the future, and the lines of railway and other communications which form the arteries of the country, besides connecting it with adjacent territories. Let me say that probably all who know the country will agree that it is certainly not suited, except perhaps in one or two comparatively small patches, for European settlers on colonial, *i.e.*, farming

and ranching lines. It is rather low lying, rarely exceeding 4,000ft., essentially tropical, and by no means a health resort. It is, therefore, a country clearly destined for development on a carefully balanced combination of plantation development, side by side with native economic crop production. There is no reason why these two avenues of development should be incompatible with one another. On the other hand, they can definitely support each other, but I must repeat that success and the absence of friction depend upon a careful proportion being observed between the degree to which each is stimulated and encouraged. There is sometimes not much practical difference between the grant of facilities and actual official encouragement, since those to whom the facilities are granted may not unfairly argue that they should not have been granted them had it not been intended that they should be fully effective. Practically all development in tropical Africa depends ultimately upon population. Area is counted by square miles, not by acres, and with a population of not more than 15 to the square mile, it depends only upon good administration to ensure that development, both by plantation and by native production media, will not be checked through lack of area.

I have barely outlined the great task undertaken by the British Empire in discharge of the trusteeship conferred upon it by civilisation. Time does not admit of discussing the hundred and one details with which the hands of the Administration must be daily engaged. Mineral exploration, for example, has been regulated and encouraged by the enactment of a broad mining law and the grant of prospecting facilities. Coal, which the Germans had failed to locate, has been found, but I gather that the quality is not yet ascertained. Obviously the importance to the whole of Eastern Africa of such a discovery, if confirmed, will be immense. Transit facilities for the Congo traffic have been organised, with arrangements for "in bond" transmission of goods in both directions. Township affairs have had attention, with the setting up of municipal committees at Dar Es Salaam and Tanga and elsewhere. Medical, sanitation and research departments, have been organised. Agricultural, mining and survey departments are at work. Posts, telegraphs and coastwise shipping services are restored.

The intricate matter of the change over from German to British currency has been accomplished.

All this, be it remembered, has had to be done when the whole world was out of gear, and the demand for expert and trained administrators was never so great. Unlike the re-organisation of the Transvaal by Lord Milner, after the South African War, it was not the question of taking over from an ex-enemy Government already functioning. Nor could it be quite a matter of creating a new organism from the egg. True, the egg was there, but it was badly addled. A new egg has had to be laid and hatched, and we, as Englishmen, may feel proud that the chicken bids fair to grow up a strong and healthy bird.

May I just say a word respectfully to those, for there are some, who are disappointed that progress has not been even more rapid, especially in commercial activity, and land development? Some complaints of official lethargy, and even of obstruction, have been made and published by a few individuals in the Territory. Their remarks have been carefully noted in Germany, where there are many only too ready to turn them to account. About a fortnight ago, Dr. Scholle, the Director of the German Colonial Society, referred to these complaints, at a meeting held, I think, at Leipzig, which was attended by most of the ex-Governors of the old German Colonies, among them Dr. Schnee, ex-Governor of East Africa. What better proof, said Dr. Scholle, can the world need of the justice and necessity of the restoration of her colonies to Germany, for which event, he added, every loyal German must never cease to work, than the fact that even British residents in Tanganyika Territory are complaining of the British Government? How much better, he implied, would matters be if the Germans resumed the administration. Now, I hold no brief for the British Governor of Tanganyika and his colleagues, save that which every Englishman should hold, viz., to support in every possible way, those men of our race, and those principles of our tried and proved system of African administration, that have kept the name of Great Britain clear before the world. Those men are laying the foundations of a great British dependency. The British East African group of countries, of which the ex-German Colony is now a definite component element,

has a population of 12 million people. In 1822, the United Kingdom held one million less than that. To-day these Islands hold nearly 50 million inhabitants. With the Pax Britannica, the British pharmacopeia and good Government, that British East African group of African countries will, in a hundred years from now, have probably a population of 50 millions. And what is 100 years in the history of the world? What, if Great Britain proves worthy of her place, will 100 years be in the history of the British Empire? The Roman Empire in Africa covered 600 years of time. In less than half that period, tropical Africa will have her hundreds of millions of British native subjects. Will they be a blessing to the world, or a curse? There can hardly be a midway result. What is done during the next few decades will probably decide the answer. Great, indeed, is the responsibility that rests upon the present generation. Let us, therefore, wholeheartedly support those men of our race who are carrying the torch, cheer them in their task and thank them for their devotion.

DISCUSSION.

THE CHAIRMAN (Sir Frederick Lugard) said the meeting had had the pleasure of listening to an extremely interesting paper, full of facts and the stored experience of a man of affairs, who was a competent critic. He thought everyone would agree with the general conclusions the author had arrived at; personally he heartily agreed with practically everything that Sir Humphrey Leggett had said. He had described the German Akida system, contrasting it with the method which had superseded it under British rule. A similar system had formerly existed in the Mohammedan States of Nigeria, where the rulers employed "Jekadas" to collect taxes and forced labour. Bad as that system was in Nigeria, it was a thousand times worse when enforced as in German East Africa by a European power with organised troops. What the rebellion against that system meant was shown by the statement that in 1905 something like one hundred thousand men, women and children were done to death.

The second conclusion at which the author arrived was that to encourage the native to be a producer was better than making him a mere wage-earner, in the position of a serf or slave. Under the system of native production, the natives would gradually emerge from that bondage of slavery to which for so long they had been accustomed, and gain the idea of independence and freedom. Apart from the

moral aspect, he thought that the system of native cultivation was sound economic policy. As Sir Humphrey had remarked, the Germans had been forced to admit that that was the case, and to adopt that system to some extent. For the success of such a policy it was essential that the Government and the merchants should co-operate.

In this connection he might say that if all the big estates formerly owned by German planters and now advertised for sale were sold to European purchasers, it would seem as though the British were perpetuating to some degree a system which they condemned when it was practised by the Germans. If the supply of labour was insufficient under German rule, it would be much more so when the estates had to be restored to the condition in which they were before the War. When, in addition, the author estimated that an annual production of 100,000 bales of cotton should be looked for, the difficulties in securing labour for the big estates as well could be realised. He had no doubt that that had been considered by the Colonial Office, and he hoped that some of the estates would be restored to the natives, only such a number being sold to European purchasers as could be adequately supplied with labour. In that matter Sir Humphrey was evidently in agreement with him, for he said that the plantation interests should be resumed only on a carefully limited scale.

It was mentioned in the paper that there had been a good deal of criticism of the local Government and of the Colonial Office for, it was said, going too slowly. The British taxpayer had, during the last three years, given something like two million sterling for the development of the Tanganyika territory, and he thought everyone would agree that the present was not the right time for trying to push ahead too fast.

Under the Mandate system, equal opportunity in trade and commerce was given to all members of the League of Nations. Personally, he would like the Germans to go back to their old country as traders so that they might see how matters were managed under a different system of rule. He wished to ask whether anything was being done about what were called "mean whites." It had been said that of the 5,000 Europeans who were present in the pre-war period, 1,200 consisted of Greeks, who were hardly considered white men by the Germans. He had come across the same class of Levantine Greeks in Abyssinia, where they had introduced distilleries and a low commercial morality. He hoped that some steps would be taken to prevent the entry of that class of European into the territories inhabited by primitive races.

SIR GEORGE C. BUCHANAN, K.C.I.E., M.Inst.C.E., said he gathered that there was now an opportunity of starting with a com-

paratively clean slate in Tanganyika. Much depended on the initial policy. He thought every one would agree that there was ample room for development, both by the plantation system and by natives working on their own land. Fortunately, Tanganyika was not hampered by the delusion which existed in Kenya, that it was what was termed a "White Man's Country." The first essential of a white man's country was a climate in which the white race could breed without deterioration and where children born and bred in the country would grow up as strong and vigorous mentally and physically as their grandparents. He understood that that essential was unobtainable in the tropics, where the climate, though cool in the hills, was not temperate. If, then, it was decided to encourage and stimulate the native producer, as was done in India, Uganda, and on the West Coast of Africa, as a natural corollary, he must be given an inalienable right to his land. In Kenya that was not yet the case, and at a recent meeting of the Convention of Associations, where native affairs were discussed, it was stated that there was no greater source of native unrest than the land question. The natives had no security; time and time again the Government had promised not to take any more land, and as often the promise had been broken. It was to be hoped that that would not occur in Tanganyika. In the matter of the development and equipment of the country, railway and road communications and port facilities came into the forefront. For those essentials large sums of money were required, and the question naturally arose: Where was the money to come from? The author had said that large grants in aid had been made by this country; in other words, the already over-taxed British taxpayer was being called upon to pay for the upkeep of countries about which the majority knew little and cared less. The railway was being run at present at a dead loss of something like £100,000 a year, and it was unlikely to pay until further developments took place. The ports required developing on modern, but not necessarily extravagant lines. He hoped a lesson would be learned from Kilindini, where about one-and-a-half million pounds was being expended on a two-berth wharf. The Colonial Office would be well advised if they invited the assistance of private enterprise to develop the railways and ports of Tanganyika. Lord Inchoape had said in a recent speech that during the investigations of the Geddes Committee he had been more than ever satisfied that it was a fatal mistake for any Government to embark in trade or business of any description, and that the proper and only functions of a Government were to maintain law and order, provide adequate defence, exercise rigid economy and tax all sections of the community fairly. Unfortunately, Governments did not always take that view, and pre-

ferred Government control, however expensive. A tendency to public extravagance was one of the unfortunate legacies of the war. Schemes were promulgated because they were bold and appealed to the imagination, regardless of ways and means, and when the bill came in it was too late to remedy the evil. Nothing was easier than to spend other people's money, and the bringing in of private capital for development would have a sobering influence.

MR. ALFRED WIGGLESWORTH said that having had an opportunity of visiting Tanganyika before the War and studying the situation there, he could vouch for the immense labour which Sir Humphrey Leggett must have performed in getting together so many facts regarding the German method of administration, and in giving an up-to-date statement as to the situation of the Colony under British rule. There was, as he had said, considerable criticism of the Local Government, especially in Tanganyika itself. He thought those who were responsible for that criticism had forgotten, to a large extent, the difficulties under which the Government laboured in taking over the Colony, which had lost all its traditions and all its records. Those who had previously administered the Colony had left before the British took it over, and the legal system had entirely broken down. What rendered the task more difficult was that owing to the Mandate system not having been properly evolved until almost two years after the Colony was taken over, it had to be administered without any Mandate whatever. The author had briefly discussed the meaning of a Mandate. The authorities admitted that even under a properly constituted Mandate, the King had no power to appoint judges; he could only appoint them for territory administered by the Crown. That caused an interminable delay and a great deal of legal argument. During the *interregnum* the Greek gentlemen to whom the Chairman had referred took every advantage of the situation and put the commerce of the country in a very serious condition. The clock was thus set back by many years. It was only now when the Courts had been properly constituted, and the estates, to a large extent, had been assigned to responsible people, that headway was beginning to be made. The Chairman suggested that some of the estates should be reserved for the natives, but he could not see how they were going to find the money to buy and carry them on. Most of the estates that were being sold were 10,000 to 20,000 acres in extent, with machinery, equipment and organisation only workable by Europeans. The Germans would not allow anyone to buy an estate until he obtained a certificate to state that he had made arrangements for an adequate supply of labour, and that he had raised the necessary capital

for the development of the land within a certain number of years. That method was one which could very well be adopted by the present Government, so as to prevent the leasing of land to people who would only hold it for a speculative rise in value, or who might not have the necessary funds for development. In alienating to the Belgians the two provinces in the north west corner of the territory, a very valuable asset had been allowed to disappear. The provinces in question were amongst the richest in the whole territory, and, as Sir Humphrey Leggett pointed out, contained three-and-a-half millions, or approximately 50 per cent. of the population of the entire country. The Germans had been looking to those provinces as a recruiting area for native labour.

The fact that no British ships called at German East African ports was due to a useful arrangement between the Union Castle Line and the German Lines not to touch each other's territory. Prior to that agreement the Union Castle boats called regularly at Tanga and Dar-es-Salaam. The Germans had a system of small coasters calling at the little isolated ports which ocean liners could not reach and picking up cargo, which was transhipped without having to be put into lighters. That was of enormous importance and might well be adopted at the present time. African produce was being sold at the lowest possible price, and unless every penny was saved on manufacturing and transit, profits could not be made, and without profits the development of the country could not go on. The country had depended far too much on grants-in-aid from Great Britain that could not be continued indefinitely. The author stated that the total German exports from the province amounted to approximately £2,000,000. He was rather frightened to find, therefore, that the Government expenses for the year 1921-22 were £1,920,000. The German expenditure was much less than this amount. The territory had been set back very considerably by the War and delay in reconstruction, and it would be a very long time before it arrived at the position which it occupied in 1914. If it was going to show results that would justify British merchants in spending money to develop it, the expenditure on administration must be enormously reduced. If Tanganyika was to be properly developed, wages would have to be adjusted and would have to come down to a point which would render competition possible. The natives could not start plantations on their own account. If they were handed cotton seed, they would plant it and hand over the produce, but they could not grow sisal, coffee or any large products. The splendid Biological Institute at Amani, two or three thousand feet up in the hills, did extremely valuable work before the War. It was thoroughly well-organised and had been of

great assistance in guiding the German planters along successful lines. It was half the battle of successful tropical development to know what was going to succeed and what was not, and ruthlessly to cut out all failures.

SIR JAMES CURRIE, K.B.E., C.M.G., said Sir Frederick Lugard had told them that one of the first things to be put right was the existing land system. It occurred to him that the Chairman had gone rather farther than Sir Humphrey had intended with regard to the plantation system. He would like to know whether he was correct in that surmise or not. He entirely agreed that native ownership and native development must form the basis of the Colony's progress, but it was important not to overlook the fact that every well-run plantation under European management was a fine technical school, to call it nothing else. He did not think that in any country an unlimited system of small holdings, and a complete absence of large estates, was desirable. In Vanderlip's book on European Problems the extraordinary fall in production and agricultural efficiency in various parts of Eastern Europe was ascribed very largely to the smashing up of big estates and the universal introduction of peasant proprietorship. It was quite possible for the pendulum to swing too far in either direction. He did not believe that South Africa would ever obtain her maximum production of staples until she scrapped the policy which obtained there, and rendered it possible for the native to settle on the land with more freedom than at present. That did not persuade him, however, that a complete elimination of all large estates would be opportune or wise, and he hoped that a certain number would always remain in existence. A great deal had been heard about the danger of high expenditure, but surely that depended on what the objects of that expenditure were. He had the pleasure of hearing the President of the Board of Trade say the other day with regard to the creation or re-creation of potential markets for the export trade of this country that he would much sooner put money into our own colonies than continue fooling with policies of reconstruction in Eastern Europe. He would like to ask whether the great bulk of the population of Tanganyika territory were Mohammedan or Pagan?

MR. DONALD MELLOR, F.R.G.S., said he had to deal with travel in Tanganyika Territory and was especially familiar with the railways. It was remarkable that the central line from Dar-es-Salaam to Kigoma was not thought so much about as it ought to be. He believed that at the present time there was an enormous traffic going along it to the Belgian Congo, and it was natural to suppose that there would be a certain amount of traffic going back over that line from the Belgian Congo until the Belgians

properly developed lines of their own towards the Atlantic. He would have liked to hear a little more about the country between Victoria Nyanza and Tabora. He did not know whether a road existed between Tabora and Mwanza, but he had heard lately that there were two routes between those points. That was of great interest from a traveller's standpoint, because several people had made journeys from Cairo to Cape Town via that route. One could go from Tabora to Cape Town by rail and steamer all the way, and it was possible to go from Dar-es-Salaam to Cape Town by that inland route in 25 days. It was of interest to note that the Belgians had just launched a 350-ton steamer on the lake, which would make things better for passenger traffic and trade generally. Something had been said about the grumbling out there. He hoped that the railways would, as far as their resources went, develop the line and the rolling stock, and bear in mind that to put too high rates on the traffic would certainly be disadvantageous to the development of the colony. Many people forgot the work that the men out there were doing and the influence they exercised over the natives, an influence which had raised the British name wherever British people went. He trusted the officials in Tanganyika Territory would not be altogether forgotten.

SIR HUMPHREY LEGGETT, in reply, said the discussion had been one of the most interesting he had ever listened to. With regard to the Chairman's question as to "mean whites," he understood there was a financial condition attaching to immigration which was strictly enforced, and he believed that at the present time an enquiry was made into antecedents if there was the smallest doubt as to the desirability of any individual. The only remedy, he thought, was to make it known as widely as possible that the opportunity of "getting rich quick" did not exist in East Africa. If that was done such people would not come. Everyone would agree with Sir George Buchanan's remarks on the openings which should be given to private enterprise. Subject to proper supervision, it was most desirable that private enterprise should be encouraged. Such concessions as a monopoly of the lighterage at the ports, which the Germans granted, were not desirable, however. There might be special circumstances in a mandated country such as Tanganyika which demanded exceptional consideration, in view of the fact that the raising of loans on the security of the country itself might not be feasible for some time to come; it was undesirable that the country should be held back by absence of capital for necessary public works. Sir George Buchanan had mentioned the matter of land set aside for natives. Personally, it was his view that the whole area was a native country. He detested the expression "native reserves"; he thought

that land not in tribal occupation might be set aside at the disposal of the Central Government, so that it could not be taken up and misused by any one—white or black—but the idea of delimiting native reserves and saying all the rest was European was putting the thing the wrong way round.

With reference to Mr. Wigglesworth's remarks, he agreed there were many juridical difficulties appertaining to a mandated country, such as right of appeal to the Privy Council and so forth. These must take time to settle. Mr. Wigglesworth also mentioned the subject of reserving land from sale, and asked how it could be sold to the natives. If the Chairman's proposal were adopted, as he hoped it would be, and the whole of the alienated lands were not sold, it did not follow that the Government would sell the land to the natives. If the lands alienated amounted to, say, one million acres, and it was decided that not more than 750,000 acres should be resold, the remaining 250,000 would remain in the hands of the Mandatory Power. The question might then arise as to the value of that unsold land being credited to the Reparations Fund. He thought the difficulty might be got over in the following way. Some of the land grants had been immense, far greater than were likely to be fully used, and some of the more remote ones might, therefore, be divided into two, and only the more valuable portion sold. Three or four thousand acres could be lopped off a ten thousand acre estate quite easily, and that residue would then have a low value and might remain the property of the Central Government without payment. He was of opinion that economic balance was likely to be achieved in a very short time. If it became a question of pushing either the plantation interest or native-grown produce, he thought preference should be given first to the latter, as quicker returns would be obtained therefrom during the next two or three years, while the plantations were being restored to their former output capacity. He agreed that the Institute at Amani was most valuable. The British Government had done their best to keep it in being, and had retained some of the German scientific staff there until British experts could be sent to replace them, thus avoiding a break in continuity. Sir James Currie had asked whether the Chairman had not gone further in the matter of native crop development than he himself intended. He thought, as far as words were concerned, that was perhaps the case. It should not go out as the considered opinion of the meeting that it was wise for a country like Tanganyika to depend on native production only. He agreed with Sir James that plantations were technical schools of the highest value, and, further, they produced crops of the greatest value to the Empire and raw materials of tremendous importance to the material requirements of this country and

of the world, which could only be obtained on the plantation system. Not one ounce of sisal would ever be produced if native production alone were relied on; it required high organisation, technical skill, elaborate machinery and plantations worked in the most up-to-date manner. A carefully balanced combination of the two methods of production was the thing to aim at. Sir James Currie had also asked about the religion of the natives. There were 7½ million natives in German days, and there were now about 4 million under British rule. The German statistics showed 280,000 Mohammedans, and that included Swahili and the population on the coast; the remainder were Pagans or Christian converts. A German circular found after the war, showed that the Germans had told their District Commissioners to encourage the native chiefs to become fond of pig flesh, in order to prevent the propagation of the Mohammedan religion. With regard to Mr. Mellor's remarks, the road from Muanza to Tabora was open up to the year before last, and at that time was quite suitable for motor-car traffic. He believed it had since become somewhat overgrown, but it would no doubt be re-opened again, as it was an important line of communication. Mr. Mellor had mentioned a 350-ton steamer put into commission by the Belgians. Before the war the Germans had a 1,000-ton steamer on the Tanganyika Lake. The British Navy sent it to the bottom, but fortunately the bottom was not very deep, and within the last fortnight money had been promised by the British Treasury for raising and restoring that steamer, and it was hoped that within the next six months she would again be in commission under the British flag.

MAJOR BLAKE TAYLOR, C B E, proposed a vote of thanks to Sir Humphrey Leggett for his very able paper, and to Sir Frederick Lugard for presiding. The thoroughness with which the former had prepared his paper was what one would expect from one whose heart and soul were in the development of Africa.

ADMIRAL DE COURCY HAMILTON, M.V.O., seconded the motion, which was carried unanimously, and the meeting terminated

TOBACCO GROWING IN THE BRITISH EMPIRE.

A special correspondent of *The Times Trade Supplement* draws attention to the great possibilities of the British Empire in growing tobacco. He comments on the anomaly of an Empire possessing millions of acres of land suitable for tobacco cultivation not being able to supply anything approaching its own needs. An enormous increase in the consumption of tobacco in this country has taken place

in recent years, our imports having risen from 162,000,000 lb. in 1913 to 227,000,000 lb. in 1921.

The United States is the most important exporter of tobacco and exports all forms, particularly cigarette and pipe tobaccos, the American cigar requiring a particular taste which does not prevail to any extent outside that continent. Macedonia and the Crimea are next in importance for cigarette tobacco. What is known generally as Turkish tobacco comes from Macedonia, large quantities going to Egypt to be made into cigarettes there. The Crimea produces very important tobaccos used in the Russian cigarette blends which have grown in popularity very greatly in the last few years.

The countries producing cigar tobacco and cigars are Cuba (Havanas), the Philippines (Manilas), Mexico, Brazil, Java, Borneo, and Sumatra. From the last-named country come the finest leaves for cigar wrappers, Sumatra having almost a monopoly for the export of the first grade of this important commodity.

Tobacco growing in the British Isles has been spasmodic and is, perhaps, not likely to have any very conspicuous success. One expert explains it on the ground that to grow tobacco successfully you must grow it quickly, and that if it is left in the ground (as our temperate summers cause it to be) it becomes earthy, tobacco being notoriously sensitive to its surroundings, a fact which is, of course, utilised by scientific growers in obtaining a required aroma. Australia grows and uses a considerable quantity of tobacco, but is not an exporter to any appreciable extent. Canada has an important cigar and pipe tobacco industry, but has not yet been successful in supplying precisely the requirements of this country, although a certain quantity is now being sent here and Canadian growers are evincing a very great interest in the requirements of this market and endeavouring to meet them. Indian and Burmese cigars and cheroots will always command a certain definite market, and some Indian tobaccos have latterly been used increasingly for blending. British North Borneo, too, has come prominently into the market of this country recently; but for the future it is likely that Africa will provide the most suitable field of development. The pipe tobaccos of the Union of South Africa are already well-known and established here. Rhodesia has produced tobaccos of admirable quality, and though the industry is extremely undeveloped there the possibilities are without question great. Of East and West Africa there are endless enthusiastic reports by settlers and other observers, but few reduced to the basis of facts and figures. The general botanical information, however, in regard to both sides of the continent

would lead one to suppose that a cigar tobacco of some value can be grown, especially in the west; indeed, the writer has been told by experts in this country that samples of leaf have arrived of a quality which, with care and development, may one day rival the wonderful Sumatra wrapper leaf. But Nyasaland, more than anywhere else in the Empire, offers possibilities as the future tobacco field of the British world for cigarette and pipe tobacco. The qualities of its product are admirable, great enterprise has been shown by British concerns in that part of the world, and a considerable development of scientific production has resulted.

JELUTONG.*

The Jelutong Tree—indigenous to Sarawak—is found in old jungle in swamps at the foot of hills; it has not yet been cultivated, and there are still large districts where the trees are in sufficient quantities to provide employment for numbers more than are now engaged in this industry.

The work would appear to be particularly suited to the native population who are not possessed of much capital, a worker's outfit being of very little expense to him; however, with the usual improvidence of the Malay, these people generally require advances of cash from a Chinese trader before they will work Jelutong.

Dyaks move from their homes for long distances to districts where these trees grow, the people of Batang Lupar and Rejang travelling to the Balingean, Bintulu, and Baram districts.

The following brief description will give an idea of the method of working this produce:—

A journey is made by boat to a likely district on the banks of a river and search is made in the jungle at the chosen spot; if a clump of trees is found near at hand a path is cleared to the banks; the felled trees being laid end to end, form a path through the swamp. From this clump search is made to the next clump, which is again joined up by a path of felled trees. The system continues until from 250 to 350 trees have been discovered and joined up. This "working" is sufficient for one man and is known as a "Jelutong path." The owner registers his path at the nearest Government station and is granted a permit, when it becomes his property so long as he works it. The tapping of jelutong trees is supervised by Government which provides inspectors to see that tapping is carried out according to regulations and also that all owners and workers are registered. Previous to this control the native preferred to tap the tree to death to secure a quick profit to himself with no thought to

* Extracted from "Notes on Sarawak Trade," published by the Committee for Agricultural and Forest Exhibits, Malay-Borneo Exhibition.

the future; in fact, he even felled the trees so as to extract as much latex as possible in a short time.

Having registered his path the owner employs tappers, if he has discovered a large supply of trees, but 250 to 350 trees will provide work for one man; 40 to 50 trees can be tapped in one day, and the tapper passes from section to section until the whole "path" has been tapped; by this system a tree is tapped once in 7 days. The gouge tapping knife is used and the tree is tapped on the herring-bone system. When the tapping is out of a man's reach the gouge is mounted on to a stick.

Having tapped his 40 to 50 trees, starting at 7 o'clock in the morning, at 11 o'clock he starts collecting; for which purpose he uses an ordinary four gallon kerosine oil tin slung on his back. The latex after tapping runs into bamboo "cups," but if these are not conveniently available cloth bags are used. In the place of the usual zinc spout a jungle leaf is used, preferably the leaf of the rattan if near at hand. Sometimes cloth bags are used, both as cups, and to replace the kerosine oil tin.

If the "cups" contain more latex than can be carried in a kerosine oil tin the sides are built up with cloth, with sticks at the corners to make it rigid, thus giving additional height to the tin.

The coagulating sheds are usually built at a convenient position on the river bank, where the worker sleeps and lives.

Here the gathered latex is poured into a tub and coagulated with a mixture of 1 tahlil gypsum to 1 pint of kerosene oil, this quantity being sufficient coagulant for one tin of latex.

The coagulant and latex are stirred together for ten minutes and then left till the next morning, when the coagulated jelutong is made up into cylindrical or square blocks (beluku), which are stored in fences on the river bank by the owner's living quarters.

From time to time his stock is brought to the nearest bazaar for sale or delivery to the merchant from whom he has received advances.

Shipment is made to Kuching in steamers and schooners. On arrival it is usual for the shipment to be tendered for; the prices tendered form the local market rate until the next shipment arrives.

There is 60 to 70 per cent. of moisture in raw jelutong at the time of shipment.

European firms using raw jelutong locally have found it more economical to buy supplies through Chinese agents rather than to make advances to the jelutong workers direct.

Recently a new method of coagulating raw jelutong has been introduced, the treatment taking place in the jungle and delivery being made in the form of bricks.

Considerable quantities of raw jelutong are being refined locally by Chinese traders. The process is as follows:—

The coarser impurities are removed, and the cleaned jelutong is boiled; during this boiling

an "acid" is mixed to aid the refinement; although this "acid" is used, it is very doubtful if any process, further than extracting impurities, is necessary, the quality of refined jelutong depending on selection of first quality raw material which is quite fresh.

The "acid" mixture is supplied to the Chinese by Malays from Singapore and the F. M. S., who, relying on the credulity of the Chinese, inform them that they possess the secret of a mixture which will ensure the best quality of refined jelutong.

These men are paid comparatively large salaries or retaining fees on condition that they will not supply their mixture to others, but although the greatest secrecy is observed as to the contents of this mixture, there appears to be only one thing definitely known, and that is that the acid used in the secret mixture dissolves a quantity of the rubber content of raw jelutong and causes the refined article to be of inferior quality to that manufactured without its use

GENERAL NOTE.

FOOD PASTE INDUSTRY IN ALGERIA.—Algeria has peculiar advantages for the development of the food paste industry, writes the United States Consul at Algiers. Besides an abundant supply of cheap labour, the country raises a variety of hard wheat particularly suitable for making good macaroni. Some fifty factories make daily about 40 metric tons, employing mostly women and girls on machines and in packing. Since 1912, when the exportation of this product amounted to only 2,659 metric tons, the industry and export trade have both increased, except during 1918, when war conditions caused a slight decline. In 1919, exports amounted to 8,773 metric tons, and in 1920 to 3,129 metric tons, of which France received 2,796 tons. It is thought that, including exports and local consumption, the value of food pastes manufactured in Algeria during 1920 amounted to about 10,000,000 francs.

CORRECTIONS.—The following corrections should be made in the paper on "Irrigation Enterprise in India," by Mr. F. W. Woods, C.I.E., which appeared in the *Journal* of September 8th, 1922:—On page 721, column 2, line 20, for 187.1 read 185.7; and in line 23 of the same column for 186.5 read 185.0.

On page 722, at the end of section 41, insert the following:—"The winter-crop area, of 900,000 acres, can be irrigated by a continuous flow not exceeding 5,500 cusecs, which requires a water depth of 6 feet, or a water surface level of 181.0 in canal at head. This level is well below the lowest recorded water surface level of the river at the site under consideration."

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C. (2)

NOTICE.

EXAMINATIONS.

The results of the Stage I. (Elementary) Examinations, which were held from May 22nd to June 1st, were sent to the centres concerned on August 29th. Those of the Advanced and Intermediate Stages were issued on the 2nd and 17th of August, respectively.

The total number of papers worked in all three stages at the May-June Examinations was 35,802, an increase of 219 on the corresponding examination of 1921.

In the Advanced Stage 6,052 papers were worked: 769 First Class certificates were awarded; the Second Class certificates numbered 3,247, while 2,036 papers were classed as failures.

In the Intermediate Stage the number of papers worked was 14,313, made up of 2,751 First Class and 7,378 Second Class certificates, and 4,184 failures.

Of the 15,437 candidates in the Elementary Stage, 10,504 passed and 4,933 failed.

In the two examinations held this year, the total number of papers worked in all three Stages was 56,775, as against 51,267 in 1921; an increase of 5,508. In the Advanced Stage, the number of papers worked was 8,423. In 1921, the number was 8,125. In the Intermediate and Elementary Stages the numbers were 20,216 and 28,136 respectively, as compared with 19,093 and 24,049 in 1921.

Altogether, 38,925 certificates have been awarded. These are now being prepared and will be issued to the various Centres as soon as ready.

The printed results of the Examinations are now in the press. It is hoped to issue those of the April series quite shortly, while the May results, with the list of winners of medals in the various subjects, will be sent out later in the year.

Two examinations will, as usual, be held in 1923. The first will begin on March

16th and finish on March 28th, the second will be held from May 7th to 17th. The time table has already been circulated to the Centres.

The 1923 Syllabus will be published in a few days, and, with the usual posters, will be forwarded to all Centres without delay.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

PROCESSES OF ENGRAVING AND ETCHING.

By ARTHUR M. HIND, O.B.E., M.A.

Slade Professor of Fine Art in the University of Oxford.

LECTURE I.—*Delivered November 28th, 1921.*

INTRODUCTION AND WOODCUT.

I am not treating the subject of the Processes of Engraving and Etching as a practising engraver, but from the standpoint of the historian and critic. I am chiefly concerned with the technical character of the various processes in the discrimination of their several characteristics and limitations, and peculiar fitness for certain kinds of work.

I would begin by emphasising the three main classes of prints:—

I. RELIEF PRINTS.

II. INTAGLIO PRINTS.

III. SURFACE PRINTS.

divided according to whether the black line of the design (i.e., the part inked for printing) on the original block, plate or stone, is

I. In relief.

II. In intaglio (i.e., cut into the surface).

III. On the surface (i.e., on a level with the rest of the work).

These three divisions correspond roughly with

I. Woodcut and wood-engraving.

II. Engraving and etching on metal.

III. Lithography (surface printing from stone).

My present course of lectures will deal with I. and II. only, and even in these divisions will omit various processes which would come under II. (such as mezzotint, aquatint, and other tone processes), being limited to woodcut and wood-engraving (the first lecture), line-engraving (the second lecture), etching (the third lecture).

The first slide I am showing is one of the original wood-blocks by ALBRECHT DÜRER, preserved in the British Museum, from the series of the *Little Woodcut Passion*. It shows very clearly that with an ordinary woodcut the part which is cut away is merely the negative portion of the design; the surface of the block is inked in the printing, so that it is the lines and spaces left by the cutter in relief that are the black or positive parts of the design. The wood used is either the plank of a soft tree, such as apple, pear, sycamore, or beech, or a section of box-wood. For work on the plank, which was usual until the 18th century, a knife was used, so that woodcut is the correct term for most earlier work; for work on the harder box-wood, which may have been introduced by Papillon, though perhaps only in the plank, the graver or burin is the tool (or other tools similarly pressed before the hand, e.g., tint-tools, scorpers, and gouges). For illustration of tools and methods of work, I am showing on the screen Jost Amman's *Woodcutter* (from the "*Panoplia Omnium Artium*," 1568), a plate showing the *Use of the Graver* from the "*Excellency of the Pen and Pencil*" (1688), and Whistler's dry-point of the *Wood-engraver Paul Rioult at work* (1880). The press used for printing woodcuts is practically the same as that used for type, so that a woodcut is in its very constitution perfectly fitted for printing in conjunction with type, and on that account the most suitable form of engraving for book illustration. Line engraving and etching, and any intaglio engraving, require a different type of press, so that an illustration would always have to be inserted, or, if on the page with the type, would require a second printing. The press is illustrated on the screen in another woodcut from Jost Amman's "*Panoplia Omnium Artium*," and in an anonymous woodcut of the Dürer school which occurs on the title-page of a Herodotus printed at Paris in 1528.

I have spoken of the cutting of the ordinary *black line* woodcut as being the removal of the negative parts of the design.

Another example shown, a *Standard-bearer* by Urs. Graf, illustrates another style of woodcut, the *white-line* woodcut, in which the part cut away gives the positive of the design as white line on black. It is obvious that this style offers a greater opportunity to the artist who cuts his own design on the block than the style in which the cutting is a negative labour, which might more excusably be left to a subordinate craftsman.

The earliest prints from woodblocks which can be dated with certainty are Japanese, of 764 A.D., but it is probable that the art was known earlier in China. In Europe—and my lectures are limited to European work—woodblocks were used during the middle-ages for impressing patterns on textiles, the pattern or block cutters being called the *Formschneider*. Paper only came into common use in Europe at the end of the 14th century, and it is about that time that the earliest European prints on paper from woodblocks can be dated. During the fifteenth century woodcut was largely used for the popular picture of saints and other scriptural subjects disseminated by the monasteries, and for playing cards, which were introduced in Germany at the end of the 14th century, though no packs can be dated much before 1450. The earliest style of work, the simplest system of design cut in broad lines, is illustrated in an *Agony in the Garden* (Paris, Bibliothèque Nationale), by an unknown (Burgundian?) master, generally called the *Maitre aux Boucles*, while work of the last half of the 15th century, coloured by hand, is shown in a *Portrait of the Sultan* (British Museum). The "*Block Books*" (i.e., books in which the page, picture as well as type, is entirely cut on the wood) have generally been regarded as the forerunners of printing from moveable type, but none of them can be dated with any certainty before 1460, i.e., at least a decade later than the introduction of type-printing. But even a single leaf woodcut with text cut on the same block possesses all the essential elements of the block-book, and of these some certainly date before the earliest printed books, so that in principle at least the block-book is the forerunner. I am illustrating this class of work by a page from the *Apocalypse*.

A large woodcut, *View of Florence*, in Berlin (of about 1490), illustrates a common early use of the process for topography and maps, uses for which it was superseded

at successive periods by line-engraving and lithography. Large cuts of the sort (and another illustrated is Domenico delle Greche's *Destruction of Pharaoh's Host*, after Titian), are printed from several blocks, the various impressions being joined together.

In Albrecht Dürer (1471-1528) woodcut reaches its highest development. We speak of Dürer as wood-cutter, but, in all probability, Dürer was only the designer of his woodcuts, and this may have been the case with the majority of early so-called wood-cutters. But with black line woodcut I do not regard it as so essential that the artist should do his own cutting, as long as he designs with a clear view of the style most fitted for the process. In some of his more detailed designing, e.g., the *Holy Trinity*, of 1511, Dürer may have almost touched the limits of the true capability of the process, and in many of his later blocks, e.g., the *Last Supper*, of 1523, he reverts to the more open style of design with less cross-hatching which characterises his early work. I am illustrating his early phase in which the Gothic elements are still strongly in evidence, by the *Agony in the Garden*, and the *Riders on the Four Horses*, from the Apocalypse, the latter a wonderful inspiration, and as fitting in its conventions of style as anything he ever did. Of later work the *Taking of Christ* (1510), from the large wood-cut Passion, is a splendid example, with forms and composition already influenced by the Venetians, an influence which added mellowness and dignity to the cruder Gothic of his origin. Of Dürer's contemporaries and immediate followers, I am showing you one example of Altdorfer, who did a considerable number of small woodcuts of peculiar fascination (the *Holy Family at the Fountain*), and another of Lucas van Leyden, the most interesting of the engravers of the Netherlands of the early sixteenth century. But second only in interest to Dürer as a designer for woodcut is Hans Holbein, the younger (1497-1543). Nothing more perfect in their own simple conventions has ever been done than his two series of small cuts, the *Illustrations to the Old Testament* and the *Dance of Death*, both of which were first published in small quartos at Lyons, in 1538. Holbein's cutter, Hans Lützelburger, is among the few craftsmen of the period whose fame has remained alongside that of the designer.

The two succeeding centuries were com-

paratively barren in woodcut, but a few names stand out for mention: Jan Lievens, Rembrandt's contemporary, for some excellent portraits, and a study of trees; Dirk de Bray, for a few attractive blocks (e.g., a series of the *Months* illustrated in Dutch Views), and a greater mass of hack work, and Christoffel Jegher, for some powerful cuts after Rubens. In the eighteenth century Papillon cannot be forgotten, but rather as a craftsman than an artist of distinction. He produced countless small book illustrations (head-and-tail pieces and the like), and wrote a valuable book on the art of wood-engraving.

Book-illustration is undoubtedly the fittest sphere for woodcut and wood-engraving. Apart from the method of printing being the same for woodcut and type, a practical convenience of great value, the strength of a woodcut impression seems to be a better artistic balance to type than the more forcible prints obtained from an intaglio plate.

The Italian publishers of the late fifteenth and early sixteenth century fully realised this, and no more beautiful illustrated books have ever appeared than those of Venice at this period. The most attractive of all is, perhaps, the *Hyperotomachia Poliphili* (printed by Aldus, Venice, 1499), from which I am showing an illustration on the screen. Another interesting volume is the Mallerini Bible, printed at Venice in 1493, with little woodcuts, in which Holbein certainly found inspiration. A block, illustrated in another slide, from Pulci's *Morgante Maggiore*, Florence, 1500, shows a use of the white line, which is characteristic of Florentine work of this date. The elements of the white line are found earlier in the metal-cuts in the *criblée* manner (illustrated in a *Crucifixion* in the British Museum), and in the dotted backgrounds of a series of French woodcut illustrations of the earlier part of the sixteenth century (e.g., *Books of Hours*, Paris, 1510). But it remained for Thomas Bewick, at the end of the eighteenth and in the early nineteenth century to develop the white line to its fullest capabilities. And comparison of Bewick's work with Papillon's is generally much in favour of the former: partly, perhaps, due to the added clearness and delicacy in engraving achieved by his use of boxwood cut across the grain. His work may not rise to great artistic heights, but in its limited and somewhat pedestrian sphere, e.g., in his book of

Birds, it is very perfectly adapted to its purpose.

Bewick's more famous contemporary, William Blake, did little woodcut, but one series of little cuts illustrating Thornton's *Pastorals* (Virgil), 1820, are among the most perfect achievements in the whole history of the art. A considerable part of Blake's own illustrated books are printed from relief blocks in the manner of woodcut, but they are on metal, and for the most part etched in relief, not cut or engraved. Another charming example of the period is seen in the small illustrations to Rogers' *Poems*, 1810, cut by Luke Clennell after Stothard.

Very different in style from these are the wood engravings of the illustrators of the "Sixties," exemplified on the screen in a design by Pinwell for "She Stoops to Conquer," which was engraved by Dalziel. The manner of these illustrators, of whom Millais, Rossetti and Sandys were the leading figures, was essentially that of pen draughtsmen without very definite thought of style suited to the character of wood. But the wood engravers of that time had a skill of interpretation in the rendering of the most delicate line and the varieties of texture, that was fully able to cope with the difficult task set them. Nevertheless, in spite of the charm of much of the work done, I doubt the propriety of this style of work on wood. Modern photographic processes have largely ousted its use, and most present-day wood engravers are probably right in their return to the use of a simpler method, continuing the traditions of the sixteenth century, or such later Masters as William Blake. The return to Venice and her ideals, though treated in a thoroughly individual spirit, is illustrated in the woodcuts of the Kelm-scott press, in which Morris and Burne-Jones were the chief designers, and Hooper the best known engraver, while an even closer reflection of Venice is seen in the beautiful woodcuts of Charles Ricketts in the Vale Press. Easily first among the private presses still issuing books with woodcuts in England is Lucien Pissarro's "Eragny" Press, which started on the basis of the Vale fount, and has produced many books of great beauty.

Among the younger generation of artists there are a considerable number doing excellent woodcuts (e.g., Eric Gill, Noel Rooke, Mrs. Gwendolen Raverat, Philip Hagreen, John and Paul Nash, Robert

Gibbings) and a Society of Wood Engravers has recently been formed. With such material at their hand, it is to be regretted that publishers do not have more frequent recourse to this most perfect form of illustration. Process reproduction may give more freedom to the designer, but this freedom from convention generally leads to a license, by which the works produced bear no artistic relation to the page of type, and to the consequent degradation of the art of book illustration.

LECTURE II.—*Delivered December 5th, 1921.*

LINE ENGRAVING.

My first lecture dealt with prints from blocks cut in relief; my present and succeeding lectures deal with impressions taken from intaglio plates. In line-engraving, the line which prints black is a furrow in the plate, cut, or engraved by the graver or burin. The form and use of the graver are illustrated on the screen in a plate from "The Excellency of the Pen and Pencil," 1688. The printing requires a different press from woodcut or type, called the copper-plate press, in which the bed passes between double rollers to give the much greater pressure required. The lines of the plate are first filled with printer's ink, and the surface cleaned (so that the parts between the lines shall remain brilliant and white). The plate is then laid on the bed of the press, and, in conjunction with damped paper, placed on it and protected by blankets, is pulled through the press. The damp paper is pressed into the lines sufficiently to drag out the ink, which thus stands out on the impression in a relief corresponding to the depth of the engraved furrow. It is this relief in the line (felt by the finger passed over an impression) which gives the distinctive quality to the line of an engraving or etching, which the flat line obtained by the pen can only imitate superficially. It imparts a strength of tone quite impossible in pen work, and in the regular conventions of line-engraving an unequalled brilliance of texture as well.

In contrast with black line woodcut, line-engraving is a positive as against a negative process, as the line cut by the engraver is the positive line of the design, not the white interstices. So that, from this point of view, Ruskin was right in his premises when he claimed for line engraving that

"its line can only have its full value under the vivid first force of imagination . . . while a woodcut may be laboriously finished, an engraving on metal must be comparatively incomplete." But his conclusions are, I think, much open to question. Elaboration is justified in either art as long as the special value and quality of the line is preserved, and in its quality I think there is little doubt that line engraving can bear a more delicate elaboration than work on wood, whose style is best preserved by a breadth of treatment and simplicity of line. This is a matter which may best be considered in relation to particular engravings illustrated on the screen.

The first half dozen examples I am showing from various periods to illustrate certain technical characteristics. First, the *Peasants going to Market*, by Martin Schongauer (the most interesting of the German engravers of the 15th century before Dürer), shows very clearly the regular combination of line and short flicks which form the basis of the line-engraver's method. An example by Jan Muller, one of the most skilful of Flemish engravers of the earlier 17th century, a *Portrait of Isabella Clara Eugenia*, after Rubens, is given in two states, the first showing the engraver's* method of sketching out the main outlines with the dry-point (or by a light use of the graver); the second the finished plate, the outlines being clearly engraved and the composition completed by a very delicate and regular system of parallel lines, curves, cross hatchings and flicks. Then the famous *Adam and Eve* (1504), by Albert Dürer, the greatest of original line-engravers, also in two states, showing how the artist, after outlining the composition, completed the plate piece by piece, rather than advancing by stages throughout the whole subject as an etcher would more naturally do.

The portrait of *William Sanderson* (1658), by William Faithorne, the *Portrait of Himself* (1749), by Hogarth (issued later completely transformed as the *Bruiser*, in reply to Churchill's satirical attacks), and the *Portrait of the Earl of Arundel*, after Van Dyck, by William Sharp, are further examples showing how a plate can be developed or transformed in its various stages or states. Sharp's portrait is a good instance of the regular eighteenth century

method of beginning a line-engraving with a preliminary etching.

I will next give a survey of the historical development of the art in relation to original and reproductive work, with some particular reference to portrait and book illustration, ending with some remarks on its use and possibilities at the present day.

In its origins line-engraving was a development of the goldsmith's craft; for engraving, apart from printing, is one of the oldest forms of decoration on metal. A special class of goldsmith's work chiefly practised at Florence and Bologna in the latter half of the 15th century, that of *Niello*, in which the engraved lines on small silver (or gold) plates were filled with a black substance (niello) to show up the design, comes very near in style to line-engraving in our sense. Vasari goes so far as to say that line-engraving was a development from niello, Maso Finiguerra, the Florentine goldsmith (1426-1464), finding in the course of his work that an impression on paper could be taken, and be of value in itself. It is doubtful whether any of the Florentine nielli are as early as certain of the most primitive Italian engravings, and in any case the earliest German engravings are probably a generation earlier than Finiguerra's first work, so that the tradition that Finiguerra was the inventor of engraving falls to the ground. But even if engraving did not actually find its origin in niello work, the two processes undoubtedly closely reacted on each other's development. I am illustrating this point, and the identification of certain early Florentine engravings with Finiguerra's work (a case argued in detail by Sir Sidney Colvin in his "Florentine Picture Chronicle," and in the British Museum official catalogue of Early Italian Engravings) (1) by the comparison of a Florentine niello of a *Cupid* and a similar drawing in Florence, which had been traditionally ascribed to Finiguerra; (2) by the engraving of *Theseus and the Cretan Labyrinth*, and the drawing after the same subject from the *Florentine Picture Chronicle* in the British Museum; (3) by the engraving of *Mercury* from the early Florentine series of Planets. The *Mercury* is particularly interesting in the history of the craft, as it shows a goldsmith's shop open to the streets of Florence, in which the goldsmith is engaged engraving a large copper plate.

*An Instrument used more by Etchers, and described in my next Lecture.

One of the most beautiful of the Florentine engravings in the same manner as those already cited and attributed to Finiguerra is the *Bacchus and Ariadne*, only known complete in the impression of the British Museum. If not designed by him, it is certainly inspired by Boticelli. Another slide shows examples from two series of the *Sibyls*, (a) in the same style as the Finiguerra engravings (i.e., with a strong outline and close but rather irregular shading) called the "Fine Manner" in Florentine engraving; (b) in a broader style with regular parallel lines of shading, laid fairly openly and with a light return stroke at a small angle, called the "Broad Manner." The former is the development of the goldsmith's manner, the latter a more definite imitation of a painter's manner of drawing in pen and ink. The "Broad Manner" of Florentine work is very similar in technical quality to the engravings of Andrea Mantegna, the most famous of the North Italian engravers of the fifteenth century, whose prints I am illustrating in his *Virgin and Child* and the *Christ between St. Andrew and St. Longinus*. His work on the copper is full of subtle quality, and owing to the lightness of the return stroke between his parallel lines of shading, his plates must have soon lost their fresh bloom, so that while good impressions are very rare, later impressions which only preserve the strength of the design in the principal lines are by no means uncommon.

Early German work I have already illustrated in Martin Schongauer. I am giving another example of the predecessors of Dürer in Israhel van Meckenem's *Portrait of Himself and his Wife*. Van Meckenem was a goldsmith, not a painter like Schongauer, and less of an artist, but his work is, nevertheless, full of human interest and humour.

Albrecht Dürer, the son of a goldsmith, fills the central position in the art of original line-engraving, as he did in woodcut, and I am showing a considerable number of his works on the screen. The *Prodigal Son*, one of the most beautiful examples of his earlier work, before 1500, with its attractive Gothic farm buildings, *Peter and John healing the Cripple*, one of the sixteen subjects of the copper-plate Passion (1507-13), already showing in its treatment of composition the influence of Venetian art; the *Melancholia*, one of the most wonderful and imaginative of all his works,

packed full of detail, but none the less concentrated on that account; the *Virgin and Child by the City Wall* (1514), the *St. Anthony before the Town* (1519), these two with architecture so characteristic of Nuremberg, and the *St. Christopher* (1521). In the perfect conviction with which every line is laid on the plate, in a convention of extreme beauty and fitness in his treatment of the medium and in the imaginative force of his inventions, Dürer has never been surpassed by any other line-engraver.

Two of his contemporaries came near him in technical excellence, each showing qualities of his own hardly inferior, i.e., Lucas van Leyden (1494-1533) in the Netherlands (illustrated by the *Milkmaid*, a charming study from nature, a forerunner of the Dutch genre of the succeeding century) and Marcantonio (about 1480-about 1530) in Italy. There is less of intellectual force in either of these than in Dürer, but a certain gentleness of sentiment and delicacy of craftsmanship in Lucas van Leyden gives his work a peculiar charm, and for classic beauty of form Marcantonio is pre-eminent. One factor in Marcantonio's work that calls for comment is the reproductive side. A great part of his work was based on other masters, on Raphael in particular, but as far as we know the originals, it is never close reproduction, but a free and personal interpretation. We speak of most of the fifteenth century engraving as original, but in many cases it may only be that we are ignorant of the masters who gave the inspiration. Robetta (1462 to about 1522) is one of the forerunners of Marcantonio in Italy in whom we can trace the same individual use of other artist's designs, e.g., in his *Adoration of the Magi*, based on Filippino Lippi's picture in the Uffizi, but provided by the engraver with new elements in the group of angels above, and in the landscape with its suggestions from Dürer. It is interesting to trace reproductive art in the school of Rubens, who, like Raphael, had various engravers working in his studio. His case was one of the first systematic attempts at the sort of publicity that photographic reproduction can give to-day. Van Dyck also carried out a large scheme of reproduction by engraving, in his *Iconography*, a series of portraits of famous men, based on his paintings and drawings. I am illustrating his method by showing three stages in the making

of one of these portrait engravings, that of *Count Frochas de Fera*. First, the drawing in black chalk (at Chatsworth), then an oil grisaille on panel (in the Duke of Buccleuch's collection), and finally the engraving by Paul Pontius, which was probably directly based on the grisaille. In other cases there also exists Van Dyck's larger oil painting on which he based his further work in view of the engraved series.

I am illustrating reproductive engraving in the succeeding century by N. H. Tardieu's print of Watteau's *Embarquement pour Cythère*, and William Woollett's *Niobe and her Children* after Claude. Engraving has never reached a more remarkable subtlety and variety of tone than in the best work of the Watteau engravers, a variety that gains much from the admixture of delicate etching. In Woollett the preliminary etching shows in its worm line almost too rigid a system, with a resultant deadness of effect. The same criticism may be applied to the majority of the large reproductive line-engravers of the earlier nineteenth century, e.g., Raphael Morghen (illustrated by his *Madonna del Granduca*, after Raphael), though considerably less to the school of engravers who worked after Turner. There is far more etching than engraving on the plates of most of the Turner engravers, but the work was always finished off with the graver, and the general convention of their style justifies their being considered under the category of line engraving rather than etching. The use of steel plates in place of copper, introduced about 1820, but soon superseded by steel facing of the copper by electrolysis, made it possible for much larger editions to be printed from the plates, a matter of considerable value in the use of the art in book illustrations.

Occasional experiments of illustrated books with line engravings are found in the fifteenth century (e.g., Pendino's *Dante*, Florence, 1481), but the necessity for two printings, apart from the artistic instinct that woodcut was more suited from its style, probably prevented its frequent use. But in spite of this difficulty, it became the predominant medium for book illustration in the seventeenth and eighteenth centuries, when the tendency may have been to slight woodcut as an inferior art. This may have arisen from the fact that the wood cutters in the earlier periods belonged to the same guilds as the carpenters,

probably something less in the scale than the goldsmiths and line engravers. And a side light on the status of the line engraver is provided by an edict of Louis XIV., obtained by the efforts of Nanteuil, raising engraving to the position of one of the Liberal Arts.

The most attractive school of line engraving in book illustrations is that of France in the latter part of the eighteenth century, and I am showing three examples, one by Gravelot after Pasquier from *L'Ecole des Pères* (1765), a decorative piece by Delaunay after Eisen, from *Les Baisers*, and a miniature portrait of *Lafontaine* by Ficquet, from an edition of the *Contes* (1762). No more accomplished work in miniature portrait engraving has ever been done than by Etienne Ficquet.

In my last subject divisions I am showing a few examples of portrait engravings taken from various periods: the famous *Erasmus* by Dürer, a wonderful example of decorative portrait engraving; the *Cardinal Bentivoglio*, after Van Dyck, by Jean Morin, among the earliest engravers to combine the engraved with the etched line; the *Habert de Montmor* by Claude Mellan, distinguished by an individual style in which variety is added to the effect obtained by open parallel lines of shading, by means of a constant use of the swelling line; the *Christina of Sweden* by Nanteuil, the greatest of the French portrait engravers; the *Guillaume de Brisacier* by Masson, an example of the most extraordinary brilliance, but metallic in effect; the *Lady Paston* by Faithorne, the great English contemporary and no mean rival of Nanteuil, and the *Bossuet* after Rigaud by Pierre Isbert Drevet, of the beginning of the eighteenth century, when the attempt to render variety of texture had almost passed the limits of what line engraving can bear and still retain its strength.

Comparatively little original work has been done in line engraving during the nineteenth century, and William Blake's *Book of Job* (1825) is pre-eminent in its isolation, fit to take its place as a work of the highest imagination, done in the best conventions of the craft, beside the work of Dürer.

At the present time, the photomechanical processes have largely ousted engraving from the field of reproduction, and the medium is used little except for heraldic work. In many

respects these more exact reproductions may have helped towards a wider knowledge of the history of painting, but with all its exactness there are occasions when the artist's vision is able to render in monochrome the values of a painter's colours with much truer effect than the camera. And beyond this, the quality and texture of his reproduction is generally immeasurably more interesting than the best of the photographic processes. The few reproductive engravers that remain, such as Mr. Macbeth-Raeburn, work for the most part in mezzotint, and they have received little enough encouragement. If line-engraving is less likely to be used for reproduction work in future, I see no valid reason why certain modern artists should not try to recover the use of the graver for their original design, e.g., etchers like Gerald Brookhurst and F. L. Griggs, with their devotion to precision of line in etching. One of the few recent etchers who have returned to the graver is William Strang (illustrated on the screen in a *Portrait of Frederick Goulding*, the copper-plate printer), but his work with the graver practically corresponds in its appearance to dry-point. He had a graver hooked back at the point, after a device of his own, and pulled it through the plate as in drawing, the advantage that he claimed over dry-point being greater strength and lasting power in the line.

For heraldic work line-engraving is not likely to be superseded, though woodcut is always a good second in original book-plate design. Mr. J. F. Baddeley and the late Mr. G. W. Eve and Charles Sherborne are notable names in this field. In this relation I would recur in my last illustration on the screen to the wonderful *Coat-of-Arms with the Cock* by Albrecht Dürer, one of the marvels of engraved heraldic design. In face of this work, so perfectly convincing in its fitting use of the medium, Ruskin's dogma that an "engraving on metal must be comparatively incomplete" falls to the ground, for nothing of the real value of the line has been lost. With its qualities, so distinctive in the dignified conventions proper to its style, and in the peculiar force of the clear cut line printed from an intaglio plate, I feel convinced that the day of line-engraving in the broader fields of competition, whether for original or reproductive work, is not past.

LECTURE III.—*Delivered December 12th, 1921.*

ETCHING.

My present lecture, like my last, deals with prints taken from intaglio plates, but in the present case the furrow in the plate is bitten by acid, not cut with the graver. The popular confusion of etching with pen-drawing is still too common, etching being, of course, by derivation eating, i.e., biting with the acid. The one justification for the confusion is a superficial similarity of the etcher's style, which shows the same freedom as the draughtsman's, to pen drawing. But I have already emphasised the qualities of relief of the line printed from an intaglio plate, from which pen drawing differs so essentially in quality.

To help in the description of the process I am putting on the screen the plate showing etchers at work from the 1758 edition of Bosse's *Traicté des manières de graver*. On one side an assistant is seen covering the plate with the etching ground (a composition of various waxes, gums and resins), bringing a little silk bag of the substance in contact with the plate, which is being heated on a stove; the melted wax is then laid evenly over the surface of the plate by repeated taps with the dabbler (a small pad covered with silk or kid). In the centre this grounded plate is seen suspended from the ceiling, and another figure is passing lighted tapers beneath it to blacken the ground. Then at a table on the left the artist is seated drawing through the ground with the etching needle (a steel point of varying thickness, generally set in a handle), opening up the surface of the copper, which appears bright against the blackened ground, where the lines are required. In the background two other assistants are represented biting the plate in a bath of acid, the edges and back of the plate having first been protected by varnish. This process of biting may be repeated if necessary for parts of the work which require deeper lines, the light portions being protected by "stopping-out" varnish.

The other process which inevitably enters into any discussion of etching, as it is so used in conjunction with etching, though in its principle it is more allied to engraving, is *dry-point*. Here the furrow is obtained by means of a strong steel point, somewhat of the shape of a pencil, drawn through the surface in the same way as the draughtsman

uses a pencil. The resultant furrow is not so deep as that obtained by the graver, and the curl of metal which the dry-point throws out at the side is generally left, and not scraped away as in line-engraving. For the aim of the line engraver is clearness of line, and this curl of metal would hold ink, which adds a deep cloudy effect at the edge of the line called the burr, one of the characteristic qualities of dry-point. This burr is very delicate and comparatively few impressions (fifty or not much more) wear it away, so that late impressions of dry-points are mere ghosts of the rich earlier effect. On the other hand, the clear furrow of line-engraving or etching, particularly in plates with broad open line, will outlast many hundreds of impressions (on the copper—apart from the added life steel facing would give) without any rapid deteriorations, as long as care is used in the printing.

In the case of old master engravings and etchings there seems seldom to have been any artificial limit to editions. Plates went on being printed, in many cases after the death of their authors, very much at the mercy of the publishers or printsellers into whose hands they fell. If the plate were strongly engraved or etched it might be yielding tolerable impressions a century or more after its making. From the artistic standpoint alone there is no reason why any limit should be made, except the lasting power of the plate or block. Only the etcher who prints his own plates, a very advisable practice where anything depends on the variety of tone obtainable by leaving a vestige of ink on the surface, will come to the limit of his patience and may on that account prefer to make a smaller edition rather than leave the plate in other hands to print. But, in general, I think the ruling factor is the public, which thinks more of rarity than art, and the printsellers who correctly gauge the demand. One satisfactory feature is that destroyed plates are out of harm's way, but the future collector of, let us say, Muirhead Bone, will miss much of the connoisseur's delight in distinguishing the good from the poor impression.

The origin of etching may be traced back to the armourer's craft, in whose workshops the process of etching decoration on iron was certainly known at the beginning of the fifteenth century and probably at a much earlier period. Daniel Hopper, an

armourer, who worked in Augsburg between 1493 and 1536, was probably printing etchings from iron plates as early as 1500 (e.g., the *Portrait of Conrad von der Rosen*, shown on the screen), but there are no dated etchings before 1513, the year of Urs Graf's *Girl bathing her feet* (of which the only impression known is at Basle). Dürer made six essays in etching between 1515 and 1518, all of them on iron, to judge from the coarse quality of the line, one of which I am showing on the screen (the *Cannon*). Dry-point goes back somewhat earlier than etching, the interesting plates of the anonymous Master of the Hausbuch, of which Amsterdam has the best collection, belonging to the latter half of the fifteenth century. Whether scratched with the graver or dry-point matters less than the fact that the burr is left to give the effect characteristic of dry-point.

Dürer himself also produced three plates in the medium, the one I am giving on the screen, *St. Jerome in the Wilderness* (1512), showing an appreciation of the possibilities of the process which was not surpassed even by Rembrandt. I place in comparison with it a slide of Rembrandt's *St. Jerome by the Pollard Willow*. (1648), done in etching with touches of dry-point, interesting to show their respective treatments of the same subject, in each of which the study of a willow from nature is of the greatest truth and significance of drawing. In spite of Dürer's occasional success in using both dry-point and etching, it is probable that in their freedom of style neither really responded to Dürer's feeling for the sterner conventions of lineal style, for which wood-cut and line-engraving were the best means of expression.

After his three essays in dry-point, practically nothing was produced in the medium, except the work of Meldolla, in Italy, until the time of Rembrandt. The surface quality of Meldolla's plates, which often show cracks, is noteworthy, and has led to the surmise that he used a softer metal than copper, possibly pewter. But Mr. Strang who examined his prints with me some years ago was not prepared to accept this suggestion.

On the other hand, etching was used to a considerable extent during the sixteenth century, though it never came into its own until the succeeding century. The two examples illustrated are a charming figure subject called *St. Thais*, by Parmigiano,

and a little oblong landscape of 1546 by Hirschvogel, most attractive in its quaint conventions of curving strokes.

I am now putting before you a series of illustrations from various periods under the section of landscape, architecture, subject, and portrait, which may give a more vivid picture of the different characteristics of old and recent masters and their treatment of similar problems.

First, dealing with *Landscape*, the example by Jan van de Velde, a somewhat older contemporary of Rembrandt, a Dutch country scene in a storm of rain, *March*, from a series of the months, is done in a convention of drawing which still reminds one of the landscape of the elder Peter Brueghel and of Paul Bril. His work has a peculiar charm, the same flavour that one meets again in Wenzel Hollar, by no means alien to the style of modern landscape etching of the more imaginative style.

In Rembrandt (1606-1669) we find the most perfect conventions of drawing and etching, with an almost complete absence of mannerism. He was constantly making drawings from nature, but of some three hundred etchings only about thirty are of landscape. In some cases he certainly etched his landscape plates in the studio, e.g., the *Cottage and Haybarn* of 1641, where elements that could not be seen in the same way from one place are combined in the subject (the Chateau of Kostverloren on the Amstel, and Amsterdam in the background). But two examples I am showing on the screen are probably etched on the plate direct from nature, *Six's Bridge* and the *Vista*. The old story that Rembrandt etched the former of these plates for a wager while a servant brought the mustard, which had been forgotten, from a neighbouring village, may at least contain this kernel of truth that the artist carried a grounded plate in his pocket when in the country. The simplicity and directness of the treatment certainly favours the assumption, and if Mr. Lugt (who has identified so many of Rembrandt's landscapes in his recent book, "With Rembrandt in Amsterdam") is correct in his identifications, most of his prints come in the reverse direction to the actual scene. Now the first state of the *Vista* was probably sketched from nature, and the second state completed in the studio with certain elaboration in the mass of trees, and the addition of the signature.

There is much interesting landscape etching in the seventeenth century that I would illustrate, had I the time, particularly Claude, though his work in etching has far less importance than his wonderful landscape drawings; but in many ways the best complement to Rembrandt in landscape etching only comes in the nineteenth century, and I will skip the intervening period. At the very beginning of the last century is the series of *Views of Paris*, by Thomas Girtin, done in the last year of his short life (1802). In their early states they are etched in line by Girtin himself, a tone being added afterwards by other engravers in aquatint. The *View on the Seine*, shown on the screen, is of spacious composition, and a very sensitive quality of line. Crome is illustrated in his etching of *Mousehold Heath*, in a later state in which the clouds somewhat overbalance the rest. Without colour the balance of sky and ground is often of the greatest difficulty. Nineteenth century masters have experimented more in this direction in etching than the earlier masters, but they have not got further than Rembrandt's *Three Trees* or *Long Landscape with Farm Buildings and a Church Tower*. Perhaps Rembrandt's instinct in avoiding too much sky for the most part in etching, was the right one.

Of Turner, I am showing an example of his etchings, from the "Liber Studiorum," the *Junction of the Severn and the Wye*, one of the most beautiful of his subjects, in the tradition of Claude. But he treated the etched line as the mere skeleton of his subject, covered afterwards in mezzotint by his own or another hand, to imitate his drawings in monochrome wash. But this skeleton shows drawing of a significance that can only be surpassed by such masters as Dürer and Rembrandt. Other nineteenth century landscape etchings illustrated on the screen are *Peckham Rye*, by Andrew Geddes, of interest in its revival of dry-point (which had been seldom used with effect since the time of Rembrandt), the *Lisière de Claribois*, by Théodore Rousseau, reminiscent of Ruysdael, but stronger than any of Ruysdael's etchings in its massing of trees, the *Kew Railway Extension*, by Seymour Haden, the magnificent *Ben Ledi*, by D. Y. Cameron, and James McBey's recent *Camel Patrol*, and more imaginative work in Mathys Maris's *Enchanted Castle*, and *Death of the Woodcutter*, by Alphonse Legros, an etcher who never had the full

recognition that the great beauty of his work deserves.

As examples of architecture, I am comparing the work of Reinier Zeeman (1623 to about 1663), in his *Porte St. Bernard, Paris*, with the *Morgue*, perhaps the finest of the etchings of Charles Meryon, himself a sailor in his youth, and a fervent admirer of Zeeman, "painter of sailors." Other comparisons of old and new which furnish food for thought are Muirhead Bone with his wonderful dry-point of *Building* (1904) and Piranesi's *Foundations of the Castel S. Angelo* (from the "Antichità Romane"), and Hollar's exquisite little etching of *London from the Top of Arundel House*, with the *Minster*, a wonderful piece of architectural invention and fine craftsmanship, by F. L. Griggs.

In the sphere of subject etching Rembrandt is far and away the supreme master, and my illustrations will be chiefly from his work. I am showing two of his three etched renderings of *Christ among the Doctors*, the little plate of 1631, with something of the rather forced dramatic effect of his early work, and the far more intimate and less mannered plate of 1654. Then the most famous of all his plates, *Christ Healing the Sick* (generally called the *Hundred Guilder Print*), with its wealth of imaginative insight and human observation, the *Entombment*, of 1654, of a rounded dignity of composition that undoubtedly owes something to Venetian art, and the *Christ Preaching*, often known as *La Petite Tombe*. I am showing the latter in two impressions, as a test of quality. Both show strong dry-point burr, the plate when worn out having been reworked with the dry-point by Norblin, a skilful etcher of the eighteenth century. It is the sort of impression to deceive the unwary, but a comparison with the fine early impression will at once show how lacking in unity of tone and how comparatively patchy is the re-worked state. For further comparison of quality, I have placed on the same slide an early and a later state of the *Portrait of Rembrandt with Saskia* (1636). The later state was printed from the original plate as recently as 1906, for about eighty of the plates are still in existence in Paris, having descended from P. F. Basan, a well-known engraver-printseller of the late eighteenth century, who made a good commerce in printing his Rembrandts. It is remarkable how comparatively clear the plate appears

in its 1906 impression, but by the side of the early impression it will be noted how practically all the lines are coarsened by re-biting, and all the subtlety of chiaroscuro is lost.

The work of etchers in the last half-century, particularly in England, has been predominantly landscape, and I am only representing two artists on the screen, Robert Spence in his *Man with the Evil Eye*, an illustration to George Fox's Journal, comparing its scheme of composition with Rembrandt's *Christ at Emmaus*, of 1654, which Spence was deliberately taking as his model; and the *Return of the Prodigal* by Forain, with its spacious design and intensity of feeling.

Finally, I am showing a series of examples of portrait etching at various epochs. Most direct and immediately convincing of all are Van Dyck's plates, of whom I am showing the *Jan de Wael* and *Pieter Brueghel the younger*. All his portrait plates are done in the same open manner of pure etching, which Rembrandt to a large extent followed in his earlier work, which was being done about the same time as Van Dyck was engaged on his *Iconography*, i.e., between 1627-40. One of the most perfect of these earlier portraits of Rembrandt is the *Young Man with Books beside Him* (1637), which I am comparing with an early *Portrait of Himself* (1857) by Degas, a conscious imitation of Rembrandt's plate. In most of his portraits of his middle and later years, Rembrandt used a much more complex system of chiaroscuro, aiming almost at a painter's tone by a close mesh of etched fine. This is particularly so in the portraits of *Jan Six* (1648). I am also putting on the screen two studies from this plate, both in the Six collection at Amsterdam, the first a summary sketch in pen and ink indicating the general pose; the second a more careful study, with certain modifications which were carried out on the plate. The latter bears marks of the stylus in the main lines, showing that it had been used as the actual transfer drawing to the surface of the plate. Another plate, that of the *Old Haaring*, is one of the most characteristic examples of Rembrandt's later portrait etching, most complex in its characterisation and pulsating with life. It forms a strong contrast to the simpler handling of Van Dyck, who always emphasised some salient note, and probably achieved thereby

more convincing success by his portraits than Rembrandt, for all the Dutchman's greater depth of vision.

Finally a few recent portraits : Anders Zorn in his *Portrait of Anatole France* (1906), with its breadth of execution and luminous quality ; Francis Dodd's *Portrait of General Booth*, an excellent example of his dry-point work ; Gerald Brookhurst's *Mrs. Rushbury*, exquisite in its distinction of line, and Augustus John's earliest etched *Portrait of Himself* (1901). I have placed this little plate by John on the same slide as an early Rembrandt self portrait (*Rembrandt aux Trois Moustaches*), and though quite evidently the imitative work of a young artist, it shows a quality of its own by no means unworthy of the great etcher.

Perhaps the greatest danger to recent etching has been its popularity ; the public has preferred a bad etching to a good woodcut or lithograph, leaving these other arts a safer though less prosperous field. It is perhaps on that account that some of the best etchers are those who have exhibited least. But with work being done of the quality of John, Gerald Brookhurst and F. L. Griggs, to mention only three apart from those classics of etching, D. Y. Cameron, Muirhead Bone and James McBey, there is every reason to be proud of the achievement of the present day in etching.

RICE PLANTING IN SARAWAK.*

Of the many different tribes inhabiting Sarawak all cultivate rice with the exception of the nomadic tribes of the far interior. The methods adopted vary slightly but are for the most part of a primitive order.

The Dayaks and other inland tribes mostly cultivate "hill" rice, and for this purpose destroy large quantities of valuable timber every year. They consult the omens before selecting the farming lands for the year.

"Hill" land that has been farmed is allowed to lie fallow for at least seven years and "wet" land for three years.

Both men and women assist at the clearing, the women cutting the undergrowth and the men felling the big trees. These trees are often so large that it is necessary to build platforms from which the felling is done and in some cases large trees are left standing and only the branches lopped off and used to feed the fire which follows,

when the dead wood is burnt to manure the soil.

The tools used for clearing are of various kinds, but the "biliong" is commonly used for felling the large trees.

The planting is done at the end of the dry season, about July and August, so that the growing crops may have the benefit of the rains and the grain have a chance of ripening in the beginning of the next fine season, about April or May. If old jungle is cleared the clearing is commenced about May or June in order that the timber may have time to dry before the burning time.

Buffaloes are not used for preparing the ground except by the Muruts, Kadayans, and others living in the districts adjacent to Brunei and also by the tribes inhabiting the highlands at the head waters of the Baram, Limbang, and Trusan rivers.

SOWING.

The seed of the hill padi is planted in holes about 1' to 18" apart made by a blunt pointed stick. Three or four seeds are dropped into each hole and covered by scraping earth or ashes over the hole with the foot.

Wet padi is either broadcasted or transplanted. If old jungle has been cleared the seed is usually broadcasted, but otherwise it is transplanted from nurseries when about 6" high into holes drilled with a pointed stick.

The farms are fenced to keep out the wild pig and deer immediately after the padi commences to grow. The fences are strongly but roughly made and are generally about 6' high. When the farms are at a distance from the village it is usual to construct a farm house in which the family lives for the time being.

The weeding is more often than not left to the women and children whilst the men go hunting or in search of jungle produce.

CATCH CROPS.

Immediately after the burning, tobacco, maize, cucumbers, bayam, egg plants, etc., are planted wherever the wood ashes are thickest. These ripen and are eaten before the padi harvest. Millet is also planted on the edges of the paths and at the edges of the farm. This is done partly to keep the monkeys occupied till the owner arrives and drives them away.

THE HARVEST.

The heads of the padi seldom ripen all together ; consequently the crop is not reaped all at once, but the ripe heads are collected. The Dayaks do not use knives but strip the ripe heads with their fingers.

The padi is stored sometimes in the houses in receptacles made of the bark of large trees and sometimes in specially constructed granaries. When it is desired to convert the padi into rice it is pounded in mortars or put through a husker and then winnowed.

* Extracted from "Notes on Sarawak Trade," published by the Committee for Agricultural and Food Exhibits, Malay-Borneo Exhibition.

Crops vary greatly in quantity, the following being the usual causes of failure: an unsuccessful burning of the clearing, insufficient rain at the planting season, insufficient sunlight during the ripening period, depredations of wild animals, rats and mice, attacks of insects, etc.

Much valuable time is often wasted in the observance of "tabus," and when crops are plentiful, numerous feasts are given with the result that there is not infrequently a shortage of rice towards the end of the season. The use of large quantities of rice in the making of spirituous drinks is sometimes the cause of a shortage of food amongst the non-Mohammedan tribes.

In the absence of reliable statistics it is impossible to estimate the average yield, but a fair average for hill padi would probably be about 30 fold and for swamp padi about 70 to 100 fold.

CHINESE HAIR-NET INDUSTRY.

The hair-net business in China has had quite a history. It was established originally by Germans, who imported the nets from Chefoo into Germany and then exported them to the United States as European-made hair nets. There is still considerable export of human hair nets from China to European countries.

According to a report by the United States Consul at Tsinan, the bulk of the human hair nets supplied from China comes from the Province of Shantung, and while the shipment of such nets from Shanghai reached a total value of over £500,000 in 1921, Shanghai is only a trans-shipment port for Shantung. Chefoo, the largest producing centre sent to the United States in 1920, 856,610 gross and in 1921, 1,667,914 gross. Tsinan is the second largest producer; its shipments to the United States rose from 131,660 gross in 1920 to 512,317 gross in 1921.

When direct trade in human-hair nets was taken up with China, large quantities of imperfect, undersized, and generally poor nets were exported. This finally resulted in the establishment at Chefoo and Tsinan, by the foreign and a few larger Chinese exporters, of hair-net inspection factories, some employing as many as 1,000 operatives, where hair-net cargoes are inspected and, if necessary, the nets repaired before being shipped.

The net making itself is a home industry; the hair is distributed around in the various villages—in the hinterland of Chefoo and in the region of the Shantung Railway from Tsinan to Tsingtau—and the nets usually pass through the hands of several Chinese middlemen before they are offered by the Chinese dealers to exporters. The exporters buy the nets, inspect and repair them, and ship them. Rejected cargo which exporters refuse to take frequently finds its way to Shanghai, where native dealers attempt to sell it to export-

ing firms not specialising in the hair-net business and, of course, doing no inspection; so that quantities of bad cargo still find their way out of the country. Even "inspected and repaired" cargo is not entirely free from claims.

The hair-net business has been rather dull this year, due to the tendency of double nets to displace single nets. This has resulted from the durability of the double net, which, it is stated, wears five to ten times as long as single nets. The Consul adds that there is no sterilising process used on human hair nets shipped from the Shantung district and no sterilisation is done on any hair nets in China.

GERMAN ARTIFICIAL FLOWER INDUSTRY.

Before the war the artificial flowers made in Germany were produced by the "cottage" industries of Sebnitz in Saxony. They were made by the dozen and were not of the best quality. As the quality of these Saxon products did not compete with the high-grade artificial flowers manufactured in France, there was little fear of the Sebnitz industry on the part of foreign producers, and it was not until 1905, when the Saxon industry was about 35 years old, that a protective tariff against German artificial flowers became effective in France.

With the outbreak of the war in 1914, German exporters were able temporarily to sell cheap artificial flowers in Scandinavian and other countries, which normally were exclusively French markets for those articles. This trade only lasted a few months, however, since the raw materials necessary for the manufacture of these flowers could not be obtained in Germany. On the other hand, it was possible to purchase, particularly from Switzerland, materials, such as brocade and velvet, which are used in the manufacture of artificial flowers of the best quality. This circumstance led many German manufacturers to produce high-grade flowers, such as had heretofore been made only in France, and since that time, writes the United States Commercial Attaché, at Berlin, steady progress has been made in this industry in Germany.

In 1912 Germany exported 8,050 metric quintals of medium-quality artificial flowers, and at the present time is exporting high-grade flowers to almost all markets formerly monopolised by France. During March, 1922, Germany exported 660 metric quintals, valued at 68,528,030 marks, of which 234 metric quintals went to the United States, 265 to Great Britain, and the rest to Scandinavia, the Netherlands, and Switzerland. (Metric quintal = 220·46 lb.)

The extent to which the German industry has progressed is also shewn by the fact that scarcely any artificial flowers are being now imported into Germany from France.

GENERAL NOTES.

DROUGHT IN SOUTH AFRICA.—Mr. W. G. Wickham, Senior Trade Commissioner in South Africa, calls the attention of *The Board of Trade Journal* to the Interim Report of the Drought Investigation Commission, which since September, 1920, has been examining the serious problems arising out of the periodic droughts in the Union of South Africa. Mr. Wickham points out that the prevention or mitigation of drought is fundamental in relation to the future of the Union. The Commissioners emphasise the fact that nature, assisted by human agency, is at present converting South Africa into a desert, and giving rise to a much more serious problem than the eventual exhaustion of the Transvaal gold reef. Extensive areas of the Union are drying out, and a continuance of the process, if unchecked, must render South Africa, as we know it, uninhabitable by man. Two facts have been established. First, that a large portion of South Africa was dry long before the white man arrived, and secondly, that since the white man has been in South Africa great tracts of country have been entirely or partially denuded of their original vegetation, with the result that rivers, vleis, and water holes described by old travellers have dried up or disappeared. The Commissioners find that the kraaling of stock, occasioned mainly by the jackal, inadequacy of the drinking water facilities, the destruction of vegetation and the resulting soil erosion, which in turn diminishes seriously the efficiency of the rainfall, are the main causes of drought losses, which in 1919 amounted to not less than 16 millions. These are the direct losses and are a portion only of the total losses which are suffered.

CARNAUBA WAX EXPORTS FROM BRAZIL.—Carnauba wax, used in the manufacture of phonograph records and physical apparatus, and considered one of the best electric insulators, is a product peculiar to Brazil. While it is found as far south as Bahia, and even grows sparsely in the more temperate parts of Brazil, it thrives best (according to a United States Consular report from Brazil) in the hot, dry zones of the north-east, the chief producing States being Ceara, Maranhao, Piahy, and Rio Grande do Norte. The total exports of carnauba wax from Brazil during the past four years have been as follows: In 1918, 4,215 metric tons, worth 20,432,956 milreis; 1919, 6,224 tons, valued at 20,539,680 milreis; 1920, 3,516 tons, valued at 10,873,046 milreis; and 1921, 3,906 tons, worth 10,394,627 milreis. The chief ports of shipment for carnauba wax are Fortaleza, in the State of Ceara, and Ilha do São Jueiro, in the State of Maranhao, the wax exports of the two States sometimes taking second and sometimes third place among all of their exports.

WAX PRODUCTION IN THE ADEN DISTRICT.—After two years of inactivity, writes the United States Consul at Aden, the wax market in Aden is again active under the stimulus of a brisk demand from Europe. The largest quantities of the best wax come from the Shangkalla district of Abyssinia—one of the largest honey-producing regions. The Arabian wax, which comes from the Yemen, is inferior in quality and usually adulterated with a certain kind of fat to increase its weight. The Abyssinian wax comes in hard chunks and is usually pure. Wax is not used locally, but is all exported. The Arabian merchants pack it in bags, which weight from 3½ to 4 maunds (1 maund=28 pounds) each. Imports of wax into Aden amounted to 1,593 hundredweight in 1913-14, 3,890 hundredweight in 1919-20, and 278 hundredweight in 1920-21. During the same periods the exports totalled 1,462 hundredweight, 4,089 hundredweight, and 335 hundredweight, respectively. The United Kingdom is the principal destination of the wax exported from Aden.

REH SALTS.—In the February number of the *Journal of Indian Industries and Labour* Messrs. E. R. Watson and K. C. Mukerjee, of the Technological Institute, Cawnpore, discussed the nature and extent of the deposits of reh salts in the United Provinces, and estimated that a very large quantity of carbonate of soda existed in the soil covering a large portion of that province. In the current number the same authors deal with the problem of utilizing these reh salts and give the results of various experiments conducted by them with the object of ascertaining the best methods of preparing pure soda ash, caustic soda, sodium sulphide and other products from this indigenous material. The results of these researches and the account of the methods by which they were obtained should be of much interest to industrial chemists.

COCOA INDUSTRY OF ORINOCO RIVER DELTA.—About 5,000,000 cocoa palms have been planted during the past 10 years on the Venezuelan side of the Gulf of Paria, opposite Trinidad, and in the delta district of the Orinoco River. The results, according to the United States Consul in Trinidad, have been highly satisfactory, the yield per tree amounting to four pounds of cocoa, or about double what it is in Trinidad. The quality is very good, and usually the price received is about 10 per cent. higher than that paid for Trinidad cocoa. The cocoa from these districts is shipped to Trinidad, and from there it is exported to foreign countries. The export of Venezuelan cocoa from Trinidad to the United States is becoming increasingly important, amounting to 3,800,000 pounds, valued at about £120,000 in 1920, and 4,616,000 pounds, valued at about £92,000 in 1921.

CANTOR LECTURES.

THE MECHANICAL DESIGN OF SCIENTIFIC INSTRUMENTS.

By PROFESSOR ALAN F. C. POILLARD,
A.M.I.E.E., F.Inst.P.

LECTURE I.—*Delivered February 20th, 1922.*

Outside the realm of the Law, with which Science has nothing in common, an instrument is an arrangement of coacting parts which aids or supplements the senses in a qualitative or quantitative manner during the performance of experiment, and if we consider the true seat of the senses to be in the central nervous system we might classify the sense organs themselves as instruments, for indeed we find in an old book :—

“Then wash all the instruments of the senses, as the eyes, the ears, the nostrils, the mouth, the tongue, the teeth and all the face, with cold water.”

It is a little more difficult to understand quite what is meant by the generally accepted term “scientific instrument,” though, perhaps, it might be confined with advantage to that class of instruments which definitely measure some physical magnitude.

The above definition divides instruments into two main groups :—

A. Those which aid the senses in a qualitative manner and are used for observation only during experiment, such as microscopes, telescopes, telephones, etc.

B. Those which aid the senses in a quantitative manner and are used for measurement, such as ammeters, voltmeters, micro-meters, manometers, astronomical transits, depth gauges, scleroscopes, etc., etc.

This last group is by far the largest and most important for it is the last stage in the natural evolution of the instrument as it moves during its growth

from the conceived idea through the stage of qualitative use and experience, and the factors of this evolution are closely bound up with those of the evolution of man himself and all his activities. The fields of this growth are the laboratory and workshop and it frequently happens that the instrument of research to-day is the tool of industry to-morrow.

The design of scientific instruments embraces the application of many branches of the physical, engineering and chemical sciences as well as of the art of manufacture.

It embraces the application of physical and engineering laws to the arrangement and proportioning of instrument components for the performance of some specific function.

It calls to its aid the chemist for the suitable choice of materials of construction and it must conform to the art of manufacture so that the cost of production shall not throttle its inception.

The design of an instrument after the birth of its concept during the stages of the first modelling to the possibilities of actual construction demands chiefly considerations of a physical nature.

Later, as the design passes to the stages of serviceable construction, manufacture and, possibly, later still to the final stage of mass production, the considerations are chiefly of a mechanical, engineering, and economical nature.

It is to this later stage in design that these lectures are in small part directed.

The fundamental principles of the construction of all instruments have been laid down by Maxwell,* and so important are his words that they are worthy of being quoted in full. He states :—

“There are certain primary requisites, however, which are common to all instruments, and which, therefore, are to be carefully considered in designing or selecting them. The fundamental principle is, that

* *Handbook to the Special Loan Collection of Scientific Apparatus.* 1876. p. 3.

the construction of the instrument should be adapted to the use that is to be made of it, and in particular, that the parts intended to be fixed should not be liable to become displaced; that those which ought to be movable should not stick fast; that parts which have to be observed should not be covered up or kept in the dark; and that pieces intended to have a definite form should not be disfigured by warping, straining or wearing."

These apparently simple but pregnant words of Maxwell's may be regarded as the five fundamental axioms of design, and those who know of these axioms are aware of the difficulty of satisfying them in any one instrument.

Maxwell continues:—

"Each solid piece of an instrument is intended to be either fixed or movable, and to have a certain definite shape. It is acted on by its own weight, and other forces, but it ought not to be subjected to unnecessary stresses, for these not only diminish its strength, but (what for scientific purposes may be much more injurious), they alter its figure, and may, by their unexpected changes during the course of an experiment, produce disturbance or confusion in the observations we have to make.

"We have, therefore, to consider the methods of relieving the pieces of an instrument from unnecessary strain, of securing for the fixed parts a determinate position, and of ensuring that the movable parts shall move freely, yet without shake.

"This we may do by attending to the well-known fact in Kinematics:—

'*A rigid body has six degrees of Freedom.*' A rigid body is one whose form does not vary. The pieces of our instruments are solid, but not rigid. They are liable to change of form under stress, but such change of form is not desirable, except in certain special parts, such as springs.

"Hence, if a solid piece is constrained in more than six ways it will be subject to internal stress, and will become strained or distorted, and this in a manner which, without the most exact micrometrical measurements, it would be impossible to specify.

"In instruments which are exposed to rough usage it may sometimes be advisable to secure a piece from becoming loose, even at the risk of straining and jamming it, but in apparatus for accurate work it is essential that the bearings of every piece

should be properly defined, both in number and in position."

Before considering the kinematical proposition that a rigid body has six degrees of freedom, we must make ourselves acquainted with what is meant by a kinematical degree of freedom.

Consider a point in space. It has no dimensions and cannot therefore enjoy rotation. It has no parts and therefore only one aspect, i.e., position when viewed from any direction.

Its position in space must be referred to a frame of reference, to a system of co-ordinates.

And if we refer it to the cartesian or rectangular co-ordinate system, its most general displacement can be resolved into three motions, i.e., translations along or parallel to the three directions or axes x , y , z , of the frame of reference, which are independent of one another. These are its three degrees of freedom. If one of these is fixed in magnitude, say $x = a$ constant a , the point is confined in its movements to one plane, i.e., the plane parallel to the y and z co-ordinates. It can now move in that plane only, parallel to the two directions y and z . It has now, therefore, two degrees of freedom and has had imposed upon it one degree of constraint. If the point is further constrained to move on another plane, say that of $y = b$, it can only move in the first plane and in the second at the same time by moving along the intersection of these two, i.e., in the one direction parallel to z . Consequently it has now only one degree of freedom and two degrees of constraint. If the third and last degree of freedom be removed, z must be assigned a constant value c and the three equations

$$\left. \begin{aligned} x &= a \\ y &= b \\ z &= c \end{aligned} \right\}$$

represent a fixed point, i.e., that which is common to the intersection of all three planes. Our point has now no degrees of freedom and it has imposed upon it three degrees of constraint. It is therefore fixed.

So far we have referred to plane surfaces, but constraint may be imposed in other ways.

Instead of using rectangular co-ordinates we might have taken polar co-ordinates and assigned the condition in a single equation that the point should be confined in its movements to the surface of a particular sphere. By doing this we should be depriving

ing the point of one degree of freedom, for now it can only move in latitude and longitude on the spherical surface, and these are its two remaining degrees of freedom. In general a degree of constraint can be expressed by equating some function of the point's rectangular co-ordinates to a constant. This equation then represents a surface on which the point may lie. Three such equations will fix the point or rob it of its three degrees of freedom, for now it can only lie at the point or points where the surfaces intersect.

If the constant of any one equation be variable then the equation represents different surfaces of that particular family.

Thus it will readily be seen that the three constants, if variables, are themselves co-ordinates of the point and are spoken of as "generalised co-ordinates." So that in this sense the point has still three degrees of freedom. Instead of being regarded as having a degree of freedom along a straight line in space, it has freedom over a surface, and it requires three such surfaces to fix it.

The mathematical transformation of the general equations from Cartesian to generalised co-ordinates form one of the most powerful and elegant contributions to abstract dynamics which the genius of Lagrange achieved.

Let us now consider a rigid body. As Maxwell has said, no body in nature is rigid but yields elastically to applied forces. But for our present purpose we may ignore the small movements due to elastic change of shape and regard all bodies as rigid. A rigid body, unlike a point, has dimensions and can therefore rotate about some axis.

This condition at once introduces three more degrees of freedom.

The most general motion of the body (Fig. 1) may now be resolved into three rotations about the axes x , y , z , in space as well as translations along them, and these are its six degrees of freedom.

Now suppose we fix a point of the body: then we see that it has lost three degrees of freedom, for it cannot move along the three axes, but it can still rotate about the three axes which pass through the fixed point. So that it has three degrees of freedom left which, together with the three degrees of constraint, make up the six elements. The fixed point may, in general, be a point of a continuous surface of the body in contact with a continuous fixed surface, but it must be supposed that no sliding takes place between the surfaces.

This condition is realised in practice by the ball and socket joint of which the centre is the fixed point; so that such a joint enjoys three degrees of freedom. If two points of the body be fixed, the body loses two more degrees of freedom, for now it cannot rotate about two of the axes, *i.e.*, those perpendicular to the line joining the two points.

It has, therefore, one degree of freedom left—it can only rotate about the line joining the two points.

If a third point not in line with the other two be fixed the body is completely constrained.

Now, when one point of the body was fixed, we robbed it of three degrees of freedom, but if we allow the point to move in any direction over a fixed surface, we give it back two more degrees of freedom.

If, therefore, a rigid body be forced to move in contact with a fixed surface, it loses one degree of freedom, *i.e.*, it cannot move normally to that surface and it has five degrees of freedom left. Every successive constraint of a point in the rigid body to a surface means an additional loss of a degree of freedom, and thus six such conditions completely fix the body.

Thus, if six points properly chosen on the barrel and stock of a rifle be made to rest on six convex portions of the surface of a fixed support, the rifle may be replaced any number of times in precisely the same position for the purpose of testing its accuracy.

Design which is guided by these principles⁶ is termed *geometrical design*, and it may possibly already be seen that such design in many cases will eliminate accurate fitting with its attendant troublesome manufacturing allowances and tolerances, and will reduce the number of functional surfaces to a minimum. By thus introducing the various constraints we require,

in accordance with geometrical and kinematical principles, we achieve good design, and we shall see in the sequel that we can reduce the cost of production to a remarkable degree, whilst retaining precision of adjustment unobtainable in any other way.

The number of ways in which geometrical design can be applied is unlimited, and yet it would appear that this part of our subject is not so well understood as its great merits deserve. We shall, therefore, devote a good deal of our time to the description of the various parts of instruments which have been successfully designed on these principles, and in some cases examine the defects of the design where these principles have been violated.

Let us start with the case in which the instrument or a part of it is required to be placed in a definite position.

This will require a means of applying and maintaining six mutual pressures between the part and its support touching one another at six points. Such an arrangement is spoken of as a *geometrical clamp*.

An old and well-known form of geometrical clamp, with the six pressures produced by gravity is the three V grooves on the support bearing the legs of a theodolite or magnetic instrument. (*The lecturer here showed a model.*)

The arrangement of the surfaces is important. If one of the surfaces be removed, the corresponding point of the instrument (which now has a degree of freedom) will move in a direction determined by the other bearings. The tangent plane at the bearing should be as nearly as possible square to the direction of this possible movement. This condition implies that no two normals to the tangent planes at the bearings shall coincide, that no three shall be in one plane, and either meet in a point or be parallel, or more generally belong to the same system of generators of an hyperboloid of one sheet. The conditions for five or six normals are more complicated.

The three grooves arrangement, generally speaking, is not so well conditioned as Kelvin's clamp.

In his clamp one of the feet rests in a V groove and another in a trihedral hollow in line with the groove, whilst the third foot rests on a plane. (*The lecturer here showed a model.*)

Here, again, there are six surfaces, and

the pressures between them and the feet are produced by gravity.

One of the bearing points is on the plane, two are on the sides of the groove, and three on the sides of the trihedral hollow. Substitute for gravity a spring or a light screw and nut binding the part to its support to which those six planes belong, and we have a geometrical clamp which maintains a geometrical relation between the two far more securely and precisely than the clamps usually used by mechanics with three strong screws forced to the utmost. A trihedral hole is difficult to make, and for most practical purposes a conical hole may be used in place of it. In Fig. 2, *b*

represents the instrument with its three rounded feet *C*, *E*, and *D*, and *a* represents the support with the plane at *H*, the groove at *G* and the conical hole at *F*, but I cannot do better than quote Kelvin's* words as to the possible violation of the kinematical principle when using the conical hole. He says : —

“A conical hollow is more easily made (as it can be bored out at once by an ordinary drill) and fulfils nearly enough for most practical applications the geometrical principle. A conical or otherwise rounded hollow is touched at three points by knobs or ribs projecting from a round foot resting in it and thus again the geometrical principle is rigorously fulfilled. The virtue of the geometrical principle is well illustrated by its possible violation in this very case. Suppose the hollow to have been drilled out not quite ‘true,’ and instead of being a

**Treatise on Natural Philosophy*, by Sir William Thomson and Peter Guthrie Tait. 1890. Part I., p. 152. Foot-note.

circular cone to have slightly elliptic horizontal sections:—A hemispherical foot will not rest steadily in it, but will be liable to a slight horizontal displacement in the direction parallel to the major axes of the elliptic sections, besides the legitimate rotation round any axis through the centre of the hemispherical surface: in fact, on this supposition there are just two points of contact of the foot in the hollow instead of three. When the foot and hollow are large enough in any particular case to allow the possibility of this defect to be of moment, it is to be obviated not by any vain attempt to turn the hollow and the foot each perfectly 'true'—even if this could be done the desired result would be lost by the smallest particle of matter, such as a chip of wood, or a fragment of paper, or a hair getting into the hollow when, at any time in the use of the instrument, the foot is taken out and put in again. On the contrary, the true geometrical method (of which the general principle was taught to one of us by the late Professor Willis thirty years ago) is to alter one or other of the two surfaces so as to render it manifestly not a figure of revolution, thus:—Roughly file three round notches in the hollow so as to render it something between a trihedral pyramid and a circular cone, leaving the foot approximately round; or else roughly file at three places of the rounded foot so that horizontal sections through and a little above and below the points of contact may be (roughly) equilateral triangles with rounded corners."

If now we remove one of the planes we give the part one degree of freedom, and such an arrangement is termed a "geometrical slide." If, for example, in the above case we replace the groove by a plane so that now the two feet rest on the plane and the third remains in the conical hollow we have a "slide." The first application of this form of slide—in which the single degree of freedom is rotation about a vertical axis—was to the "azimuth mirror," an instrument of Kelvin's, which is placed on the glass cover of a compass to take the azimuth of the sun or stars to correct the compass.

The movement can be made very frictionless when the plane is horizontal by loading the instrument so that its centre of gravity is nearly over the foot which rests in the hollow.

The familiar support of the trunnions of telescopes in V-shaped bearings when the

trunnions are prevented from end play, is also an example of the geometrical slide.

It should be noted that this movement between the two pieces is precisely that of a journal in its bearing, it is precisely similar to that of the *turning pair* of mechanism. The extensive surfaces of contact in the turning pair of mechanism between the cylinder and the hole within which it fits have been replaced by point contacts on five surfaces. The allowance necessary for the sliding fit of the journal in its bearing is frequently responsible for a peculiar type of hysteresis which we shall meet with when discussing the "variance" of measuring instruments.

This hysteresis error is greater the greater the want of good fit of the turning pair and good fit in turning pairs which are manufactured in quantity require the upkeep of limit gauges and are costly to produce.

The geometrical slide is kinematically exact; there can be no variance from want of good fit, its manufacture requires no costly system of limit gauges, and its cost of production is reduced to a minimum.

The five surfaces against which five points of the movable body are pressed can be so arranged that the single degree of freedom left is a translation instead of a rotation, and there are many applications of this form now in existence.

If we remove one of the surfaces of the trihedral hollow of Kelvin's "hole slot and plane" and convert it into a V groove parallel to, or better, in line with the other groove, we are again left with five surfaces and the single degree of freedom is now a translation parallel to the grooves.

An application of this form of design was made by Kelvin* to the mechanism for the precise movement of the fourth quadrant of his electrometer.

A convenient form of the geometrical slide for manufacture, is that in which a horizontal cylindrical rod forms part of the moveable body and rests upon and slides in the two V grooves of the support. (*The lecturer here showed a model.*) In this way four points of support are secured, whilst a fifth point of the moveable body rests upon and slides along a plane on the support. A modification of this form is sometimes convenient, and consists in fixing the cylindrical rod to the support and forming the grooves in the moveable part.

*Report on Electrometers and Electrostatic Measurements
B.A. Report for 1867.

(The lecturer here showed a model.) The only parts which have to be accurately made in these two forms of the slide are the cylinder and plane, the latter being parallel to the axis of the cylinder. The grooves may be quite roughly made, as well as the fifth point of the moveable body without in any way interfering with the accuracy of the movement.

It will at once be seen how important this is from the manufacturing point of view, for it is a simple matter to grind or lap a true cylinder and plane, compared with the fitting of composite functional surfaces. It does not matter what the radius of the cylinder is as long as it is a cylinder, nor does it matter where the plane is placed as long as it is parallel to the axis of the cylinder when resting in the V grooves. The cylinder in the one case is moveable, and in the other fixed and these two forms of the geometrical slide are of service in showing how a design can be carried out in different ways.

Frequently, such alternative designs are of great utility in considering the loads to be moved, the distances through which the pieces are moved, and the amount of possible wear.

A variant of the second form of the geometrical slide described above, is that applied by Professor Dalby* to give easy and smooth movement to a certain pulley in his transmission dynamometer.

In this case, the frame A_1A_2R , Fig. 3, which houses the pulley, has the two grooves V_1 and V_2 formed upon it, making contact with a fixed vertical rod at four points. The fifth point is secured by a plane A_2 of the frame bearing on a second rod parallel

Fig.3.

to the first. At R a lever is hinged to the frame, which by being forced against a third rod parallel to the other two, by means of a spring attached to the frame maintains the necessary pressure in all positions between the five surfaces V_1 , V_2 and A_2 , and the rods, even if the rods are not quite parallel to one another. It should be noted that there can be no strain between the co-acting parts in these designs during change of temperature, for there is freedom of differential movement in any direction, though the relative movement of the two parts is constrained to that along one definite axis.

A very ingenious and striking example of the geometrical slide is afforded by the recent design of the supports for the projecting microscope and condenser systems of that magnificent instrument--the Einthoven String Galvanometer, made by the Cambridge and Paul Instrument Company. (The lecturer here showed the instrument.)

As the means of support for the two systems are identically the same, it is only necessary to describe one of them. The fixed parts are a carefully ground

*Proc. Inst. Civil Engineers, Vol. cxxll., p. 47

Fig 4.

cylinder A and a plane B, shown in Fig. 4, which represents the part section in side and end elevation of the projecting microscope system. The microscope C is attached to the frame D, which makes contact with the cylinder A at four points by means of the four screws E_1 , E_2 , E_3 and E_4 . These four contacts are maintained by gravity assisted by the vertical component of the force of the stretched sloping spring S_2 . The horizontal force component of this spring serves to maintain contact between the frame D and the end of an adjusting screw T, rotation of which will cause the frame and microscope to move accurately parallel to the axis of the cylinder A. To prevent the possible communication of wobble of the screw T to the frame, a short connecting rod is inserted between the two pieces. We shall return to this detail of design later. The fifth point of contact is made by the end of the screw E_5 against the plane B and is kept in contact with it by the spring S_1 .

With this simple arrangement it will be seen that the most precise setting of the microscope axis can be achieved. It can be made parallel to the axis of movement, *i.e.*, the axis of the cylinder A by the screws E_1 , E_2 , E_3 and E_4 , and it can be made to cut the "string" of the instrument when in a state of repose by the screw E_5 . The only setting which has to be done in manufacture is that of securing parallelism between the axes of the two cylinders A on either side of the "string" for the microscope and condenser systems respectively, and in this particular case it is not even necessary to set the two planes B accurately parallel to the axes of the cylinders.

If this beautiful design be compared with the older design of this part of the Einthoven String Galvanometer, it will be apparent how very much more simple it is to manufacture. Its advantages over the older design as far as the user is concerned are those common to all geometrical designs, *i.e.*, the comparative cheapness of production, the perfection of the relative movement required and the utter unimportance of unavoidable wear on account of the possibility of all necessary adjustment.

Other examples of the geometrical slide applied to the design of scientific instruments are to be found in several of the productions of the Cambridge and Paul Instrument Company, some of which have been described by R. S. Whipple.* In particular, I cannot

refrain from calling attention to the beautiful design of the slide for the carriage of the large cathetometer made by this firm, and it will be noticed that the point contacts have been purposely expanded into small functional surfaces, for the purpose of sustaining loads under which so-called point contacts might become permanently deformed. We shall return to this question of the point contact in geometrical design later.

Of all the smaller manufactured scientific instruments in which the relative movement of the parts must be of the highest order of precision, possibly the Michelson and Fabry and Perot Interferometers made by Adam Hilger, Ltd., stand pre-eminently first.

It is sufficient for our purpose to state that the chief object of the mechanism in these instruments is to move an optical mirror along an axis of some ten inches in length with such accuracy that the normal to the mirror will not wander about its mean direction when the mirror is at any part of the slide by more than 5.10^{-6} of a radian.

The carriage which carries the mirror is geometrically constrained to move along the slide which is a steel forging of channel section, with the slide surfaces formed in the upper and one of the side faces. These slide surfaces are worked to an *optical flat*, and the carriage for the mirror has a three point contact with the upper surfaces and a two point contact with the side surfaces maintained by suitable spring pressure upon the opposite surfaces of the slide, which need not, of course, be very carefully formed. This is the usual disposition for a geometrical slide, but the particular point of interest to us is the form and extent of the so-called point-contact surfaces of the carriage. These surfaces are small cylindrical studs let into the carriage with their exposed flat ends bearing against the steel slides; but in order that dust shall not collect between the sliding surfaces and tilt the mirror, it has been found necessary to clear away the metal from the central portion of the stud surfaces so as to leave an annulus of metal in contact with the surface of the slide.

The simplicity and cheapness of production of most forms of geometrical design, however, is due to the fact that the constraint is produced by the pressure of a point against a surface, and therefore at the most only two of the elements of constraint have to be carefully worked, not with the object of accurate fit, but with the object of accurate

Trans. Optical Soc., Vol. xxii., p. 35.

geometrical shape which, from the constructive point of view, is an entirely different proposition. As a rule the worked surfaces take the form of cylinders or planes which can be comparatively cheaply produced by grinding to sufficient accuracy for most purposes.

Now it must be clearly understood that this so-called point of contact is not a geometrical point at all, but a definite area the dimensions of which depend upon the pressure, the form of the elements in contact and the elastic constants of the materials. Hertz* was the first to give us a mathematical expression for the dimension of this area as well as to show in what way the stress is distributed about the point of contact between the two bodies. The matter was taken up later by Huber and Fuchs, and recently Professor W. B. Morton** and L. J. Close have contributed a paper on this problem of considerable importance to the geometrical design of scientific instruments, as well as to some questions in metrology.

When the pressure is greater than one point can conveniently stand the geometrical design can frequently be pushed to more than one point of contact for a given constraint.

But immediately we do this the geometrical principle is violated and at once it becomes necessary to introduce accurate and more expensive manufacture.

Cylinders, planes and spheres can be cheaply and accurately manufactured, however, so that construction of instruments can be greatly simplified by this application of compromised geometrical design.

A good example of this is shown in the use of the sphere cylinder and plane in the slide of the carriage of the Wickman Universal Gauge measuring machine, made by Messrs. Alfred Herbert, of Coventry.

In this machine the top carriage, which weighs 75 lbs., moves accurately along an axis over nearly four inches.

Fig. 5a shows the under side of the top carriage and Fig. 5b the top surface of the main bed, and the relative motion takes place between these two parts. On the latter, two pairs of $\frac{3}{4}$ inch hardened ground and lapped steel cylinders are mounted as shown in suitable seatings. On the under side of the top carriage a similar pair of cylinders and a hardened, ground and lapped steel flat are mounted and so placed

Fig. 5a.

Fig. 5b.

that when the top carriage is positioned upon the main bed the two pairs of longer cylinders come opposite one another and the flat faces the middle line of the pair of shorter cylinders. To complete the slide all that is necessary is to insert two balls between the two opposite pairs of cylinders and one ball between the other pair of cylinders and the flat. There are thus five points of contact between the balls, cylinders and flat of the top carriage, whilst the cylinders of the main bed merely guide the balls when motion takes place.

In the actual example before us the number of balls has been increased to nine in three groups of three each, to reduce the pressure at each point of contact.

In spite of the weight of the top carriage the makers state that it only requires the pull of $1\frac{1}{2}$ ozs. weight to set it in motion, and consequently not only is the movement truly rectilinear, but what is equally important, the pressure on the measuring anvils can be made extremely light.

It will be noticed that the two castings require no accurate machining, and it is a comparatively simple matter to secure parallelism between the elements on each.

If still greater pressures have to be taken by the relatively moving parts the point contact can be made plane contact. But

**Miscellaneous Papers* (English Trans.) p. 146.

***Phil. Mag.* Vol. 43, 1922, p. 320.

we then increase the difficulties and cost of production, for now the surfaces of constraint are true component functional surfaces of ordinary mechanism and in order that the virtue of geometrical design shall be maintained in so far as the elimination of unnecessary strain and aberrations in the geometrical relation of the parts are concerned, these surfaces must fit accurately in all positions of the moving piece.

A good example of this is the ordinary V and plane of the bed of a lathe for the traverse of the saddle and loose head stock, so familiar to most of us.

It frequently happens that in the design of an instrument extremely accurate slide motion is required with a minimum of frictional resistance in which the moving part has considerable weight or is subjected to large forces tending to separate the pieces. I have known cases in which the instrument has had to be abandoned on account of the excessive forces required to set the pieces in relative motion and which would introduce aberrations in the recording mechanism, and undesirable wear. The general question arises as to whether it is possible to replace the sliding pair entirely by turning pairs, and I think a general answer can be found in Sarrut's mechanism.

It is commonly believed that the production of a straight line motion was impossible until the problem was solved by the invention by Peaucellier of his inverting cell. But eleven years before Peaucellier's announcement, Sarrut in 1853* solved the more complete problem. All the straight line motions which were produced after and stimulated by Peaucellier's invention gave rectilinear motion to all the points of a line in one of the pieces parallel to the hinge-lines, or else to all points of a hinge-line connecting two pieces. Sarrut's solution, which embraces Peaucellier's invention, gives rectilinear translation to a whole piece.

Fig. 6.

The mechanism may be briefly described as follows:—In Fig. 6 the pieces A and B

are connected together by means of the four pieces R S T and U, which, when separated at T U and spread out on the flat, appear as shown in the diagram to the right.

The pieces R and S are connected together and to the pieces A and B by means of three parallel horizontal hinges. The pieces T and U are also connected together and to the pieces A and B by means of three parallel horizontal hinges whose common direction differs from that of the former three hinges. It is readily seen that the piece A will have rectilinear motion with regard to B, and what is important from a constructional point of view, the pieces A and B are rigidly parallel to one another throughout the whole motion.

If A, therefore, represents a part of an instrument which is required to slide with regard to the frame work B, we have here a satisfactory means of replacing the sliding pair by wholly turning pairs represented by the hinges in the model. (*The lecturer here showed a model.*)

There can be no doubt that Sarrut's mechanism, which was not appreciated for 50 years until Bennett* generalised upon it in 1905, will play an important rôle not only in instrument design, but machine design of the future.

Bennett's generalisation of Sarrut's mechanism is of considerable interest and should be noted, though its practical application may not be of much utility at present. Bennett points out that as seven is the normal number of pieces in a closed kinematic chain necessary to ensure freedom of one degree, the mechanism of Sarrut belongs to a special class of mechanisms, with only six pieces possessing singularly and exceptionally one degree of freedom.

He finds that Sarrut's mechanism is a special case of the more generalised form shown in Figures 7 and 8. The pieces A B are connected together by means of the hinged pieces R S T and U as before, but if the axis of the hinges connecting A' R S B meet at a point X and the axis of the hinges connecting A T U B meet at Y, then the piece A will have a motion of pure rotation relative to B about the line X Y. (*The lecturer here showed a model.*)

The mechanism, like Sarrut's, possesses one degree of freedom, and is made up of six pieces, and it is useful to note that it may be regarded as composed of two

*Comptes Rendus, Paris, 1853, Vol. XXXVI.

*Phil. Mag. Vol. ix., 1905, p. 803.

Fig. 7.

Fig. 8.

spheric mechanisms each of four pieces, placed in tandem with different centres.

If now the hinges connecting A R S B and those connecting A T U B be made parallel, the points X and Y go to infinity, the piece A rotates relatively to B about an axis at infinity, i.e., A has rectilinear motion relative to B, and Sarrut's mechanism is the result.

Fig. 9.

If only one of the points, say Y (Fig. 9) is sent to infinity by making the hinges of the pieces A T U B parallel, we get a third mechanism, in which the piece A rotates relatively to B about a line parallel to the hinges of pieces A T U B, and passing through the point X the meet of the other hinges. (*The lecturer here showed a model.*)

Although Sarrut's invention is even now not generally known, it is interesting to observe that it did not escape the general fate of all inventions. It was reinvented more than once.

In 1880 Brunel took out a patent for it,* and in 1891 Professor Archibald Barr again invented it.**

We should do injustice to this part of our subject if we omitted to mention the ingenious microscope which was constructed upon geometrical principles by the late Dr. Keith Lucas when a boy at Rugby School between 1893 and 1898, in a home workshop during the holidays with a scanty supply of materials and few tools.

This instrument which I have here has been lent to me for these lectures by Mrs. Keith Lucas, to whose kindness I am much indebted. It has been described by the designer in the "Journal of the Royal Microscopical Society," 1904, p. 272, but it will be instructive to examine the main features of the mechanism for the coarse and fine adjustments as well as the efficient, substage with its simple, roughly made, and yet precise arrangements.

Fig. 10.

For the purpose of the coarse adjustment the body tube D, Fig. 10, passes through the shorter and larger tube B, at each end of which is a ring C and C'. Each of these rings has two projections, Fig. 11, which serve as bearing surfaces for the tube D.

Fig. 11.

Between the two tubes a leaf spring G, Fig. 10, lies, which presses the tube D against the four bearing surfaces. This tube has

*Patent Spec. 5492, Dec. 30.

**Proc. Phil. Soc., Glasgow, March 18, 1891.

thus two degrees of freedom left—translation parallel to its axis and rotation about its axis. The latter freedom is constrained by a piece of smaller tube H, soldered parallel to the back of the tube D, passing through and engaging with a slot in the upper ring C, Fig. 11.

The coarse adjustment is effected by means of a wire J, Fig. 10, and cylindrical piece K integral with the large milled heads on either side of the instrument.

The two ends of the wire are fixed to the extreme ends of the tube D, and the wire lies within the smaller tubes. The upper end is fixed through a spring held in tension (between 5 lbs. and 6 lbs.). The wire, which will stand a breaking strain of 22 lbs., takes one turn round the cylindrical piece K. This piece has its bearings in a ring L, which embraces the large tube B. The friction of the wire round the cylinder K is sufficient to cause the up and down movement of the body tube when the milled heads are turned.

Such an arrangement has three advantages :

- (i) Small cost of construction ;
- (ii) The pull is in the direction of the desired movement of the tube and there is no outward thrust such as is caused by a rack and pinion ;
- (iii) The motion is smooth and regular.

For the fine adjustment the design is as follows :—

The limb A partially embraces the large tube B and carries four projections, two at its upper, Fig. 11, and two at its lower end, against which the tube B is pressed by means of the rod M, Fig. 10, hinged to the ring L, and passing backwards through a hole in the back part of the limb where it is secured by a nut O and spring N. The hinged joint, whose axis is horizontal, allows the tube B to move up and down through a small distance as the rod moves in or out of the hole in A. The rod thus constrains the possible rotation of the tube about its axis.

The spring P in tension between the upper part of the tube B and the more remote end of the rod performs two functions. The horizontal component of the tension is added to that of the spring N and keeps the tube pressed against its four bearing surfaces. The vertical component urges the whole tube together with the entire coarse adjustment and body tube downwards against the end of the

lever Q, shown in side view in Fig. 10, and end view in Fig. 12. This lever is of the bell-crank type, with its axis of rotation running from back to front of the limb, and bears at the lower end of its long lever against the end of a fine threaded screw, the milled head of which, situated at the left of the limb, serves as the fine adjustment.

Fig. 12.

The substage consists of a long tube E, Fig. 12, and a bracket S, attached to it, extending laterally to encounter the focussing screw T and forwards to carry the centring ring into which the condenser is fitted. The lateral extension also carries a rod U mounted parallel to the tube.

The whole substage is urged upwards against the focussing screw by a long spiral spring V anchored to the limb at its upper end, and passing through the tube E to which it is attached at its lower end.

The upward pull of the spring and downward thrust of the screw tend to cause the substage to rotate about the lower end of the latter. This couple holds the tube against its four bearing surfaces, the upper and lower pairs of which are placed on opposite sides of it. The upper pair of bearing surfaces is formed by the ends of two screws, one of which is shown at F, and the lower pair by the sides of the hole in the stage through which the tube loosely passes.

The screws, F, allow alignment of the axis of translation of the whole substage to be made optically, with greater accuracy than could be obtained mechanically.

Rotation of the substage is prevented by the rod U which passes through a hole in the stage plate. The rod makes no attempt to fit the hole, but is pressed against one side of it only, by the spring V, which is wound up for this purpose.

The spring thus causes the substage to follow its focussing screw without backlash, holds the tube against its four bearing surfaces, prevents rotation of it about its vertical axis, and allows alignment of the substage slide with the body tube.

The connection between the screw and substage is effected by a long pointed pin which passes up inside the screw so that any wobble or shake of the screw will not be communicated to the substage.

The substage bracket is not a complete ring, but a fork open at the front. This enables the centreing ring to be readily removed. When in place, this ring is held against its two centreing screws by a spiral spring stretched between the two prongs of the fork.

The advantages of this type of design are:—

- (i) Cheapness of manufacture, the turning or grinding of the tubes and the filing of the bearing surfaces being less costly than the planing or broaching and fitting of dove-tail slides.
- (ii) It is impossible for the movements to become shaky from wear, since every movement is held up by a spring.
- (iii) The alignment of the several slides is obtained optically.
- (iv) All parts are easily removed for cleaning.

This last is an extremely important point in design, which is frequently forgotten, and is consequently the cause of much annoyance to the scientific investigator, and expense in upkeep to the user of industrial instruments.

As far as I am aware, this model is the first instance in which the principles of geometrical design have been applied to the construction of the microscope, with, I think you will admit, marked success, and I am glad to be able to say that Mrs. Keith Lucas has now presented this historical instrument to the Science Museum at South Kensington. The model is rough, but it indicates a way to correct design. The microscope is the key instrument of a key industry and there possibly does not exist a more universal or more important instrument as far as the optical industry of this country is concerned.

A short acquaintance with the recent history of the mechanical construction of the microscope is sufficient at once to bring to light a state of extraordinarily erratic evolution in design pulled up here and there with retrograde steps.

At the present time probably no critical worker is wholly satisfied with any existing design and has his own ideas incorporated in some new construction.

With the mass produced instrument the state of affairs in many cases is very bad.

I have seen the bracket which carries the substage slide packed up with paper so as to bring the fitting into alignment with the tube and further to allow of side adjustment, the clamping screw holes actually file drawn in the roughest manner.

In the first place this is evidence of want of a proper system of gauging in the mass production shop and in the second place a violation of the principles of design.

The workmanship of Adam, Jones, Martin and other famous makers of this instrument in the later half of the 18th century, was second to none in the world, and this country has kept that reputation in the hand-made instrument ever since.

But a change has slowly taken place in the mechanical arts—mass production or interchangeable manufacture is now essential to secure a world market.

We shall see later, that interchangeable manufacture, which means the production of any number of pieces all exactly alike within certain unavoidable small differences, implies amongst other things a system of limits and gauges. It is essential then that the design be based on sound geometrical and kinematical principles in which the number of functional surfaces, and hence the necessary limits and gauges, are reduced to a minimum.

This is precisely geometrical design.

OBITUARY.

SIR CHARLES SANTLEY.—The Society has lost a Fellow of very long standing, by the death, on September 22nd, of Sir Charles Santley, who was elected in 1875.

Santley was born in Liverpool in 1834. The son of an organist there, he learnt to play the violin at a very early age. After a brief experience as book-keeper in a firm of leather and hide factors, he decided to devote himself to the study of music, and at the age of twenty he set off to Milan, with a capital of £40. His student days were a time of great struggle, but he had a good friend in his teacher, Gaetano Nava, and he made his first professional appearance at Milan in the opera "La Traviata," in 1857. Some other engagements followed, but he returned to England at the end of the year

quite penniless. He was then, however, heard by John Hullah, who gave him an engagement in Haydn's "Creation." His first appearance in the title part of "Elijah," a role with which he came to be so closely identified, followed soon afterwards, and led to his engagement with the Pyne and Harrison opera company, at Covent Garden, in 1859.

Santley's first appearance in Italian opera in England took place at Covent Garden in 1862, as the Count di Luna, in Verdi's "Trovatore." He subsequently transferred his services to the Mapleson management, appearing in a varied list of characters, including that of Valentine at the first performance of "Faust," which was conducted by Gounod, at Her Majesty's Theatre, in 1863. In this he achieved so much success that the composer, when the English version was brought out a year later, wrote the beautiful number known as "Di possente," specially for him.

In 1861, he appeared at the Birmingham Festival in the part of Elijah, and from that time onwards he took part in almost every festival of any importance. In 1906 he made his forty-ninth appearance at the Handel Festival, and in the following year was celebrated at the Royal Albert Hall, the jubilee of his first appearance as a public singer, when in the presence of an enormous and enthusiastic audience he was presented with a cheque for £2,000, which had been publicly subscribed. He was knighted by King Edward in the same year.

In addition to his matchless gifts as a singer, Santley possessed the most genial and warm-hearted character which won him hosts of friends. He also enjoyed superabundant vitality, and was able to take the long walks in which he revelled up to within a short time of his death.

TIMBER IN THE MARITIME PROVINCE OF SIBERIA.

There are no exact data regarding the total area of forest land in the Maritime Province of Siberia, but according to the American Consul at Vladivostok, it has been estimated that there are 490,000,000 acres of forest land in the entire Priamur District, comprising the provinces of Transbaikal, Amur, Maritime, Kamchatka, and Sakhalin. Nor is there any exact information as to the stand of the forests. In the southern part of the Maritime Province the species are very much mixed, deciduous and coniferous trees growing one next the other. In the northern part, most of the trees are of coniferous species and grow in large dense forests.

The pulp-wood industry has not been developed and there are no pulp or paper mills in this territory. The forests around De Castries Bay could supply from 2,000,000 to 3,000,000 trees annually, while Imperial Harbour, with Vanina and Data Bay regions, could supply

from 500,000 to 1,000,000 trees a year. The principal kinds of trees available for timber from the Maritime and tributary Provinces are:—Pine (*Pinus sylvestris*); cedar (*Pinus mandshurica*); larch (*Larix dahurica*); fir (*Abies sibirica*); spruce (*Picea obovata*); oak (*Quercus mongolica*); cork oak (*Quercus Suber*); ash (*Frazinus mandshurica*); walnut (*Juglans mandshurica*); aspen (*Populus tremula*); birch (*Betula alba*); witch elm; goat willow (*Salix Caprea*); and yew (*Taxus baccata*).

There is practically only one harbour for the Amur district—Nikolaevsk—into which ships over 16 ft. draft cannot enter because of the bar at the mouth of the Amur River. Before the sacking of Nikolaevsk a small amount of timber was floated down the Amur from Lake Kisi, about 150 miles from the mouth of the river. Crude Chinese methods are used. Large "rafting" is possible, however; and notwithstanding the short navigation season 3,000,000 to 5,000,000 logs could be rafted annually.

Along the coastal region of the Maritime Province, between Vladivostok and Nikolaevsk, timber can be shipped from De Castries Bay, Imperial Harbour, Turney Bay, Titukhe, Olga, Amur, and Ussuri Bays, the first two being especially good.

Timber from the Ussuri District has been sent by rail to Vladivostok and from the Sungari District by rail to Vladivostok and Harbin. However, very little timber work is being carried on at the present time.

WOOL INDUSTRY OF CHINA.

While wool is at present one of the chief exports of China, millions of pounds being sent abroad each year, the fact that the potentialities of the market are even greater than its present supply is emphasised by the United States Consulate at Shanghai, in a report on China's wool industry. Though many varieties of sheep's wool are produced, the wool generally is of poor quality because the Chinese have not adopted modern scientific methods of breeding and management. Mongolia and Manchuria offer wide fields for development of the wool industry and, while now sparsely populated, could be fully developed by taking advantage of the surplus labour in the other Provinces. Improvements in breeding and management have already been undertaken in Hunan and Manchuria and a cleaning factory established in Tientsin, has greatly increased the exports. Experiments have been conducted by the South Manchuria Railway Co., and a crossbreed between the Merino sheep imported from abroad and the native Mongolian sheep has resulted in a production of wool of twice the quality and quantity* on individual sheep. Sheep's wool from Tibet, while of better quality than that from Mongolia or Manchuria, compares unfavourably in price because of high transportation charges.

Camel's wool is produced in Mongolia and Chinese Turkestan. Russia consumes most of the yield in the manufacture of sweaters and quilts, although the United States takes a certain amount for the manufacture of carpets.

Prior to the war the United States took the entire supply of goat's wool from China, but when the war broke out the Japanese became buyers and in 1918 took two-thirds of the entire output. Tientsin is the centre of goat's wool production in the northern province and Ningpo is the market for the Yangtze yield, which, however, is inconsiderable.

PRODUCTION OF GUM MYRRH IN THE RED SEA DISTRICT.

The production of gum myrrh in the Red Sea district, during the past season, has been unusually good, both in quality and in quantity. In spite of this, an excellent demand has forced the price up nearly to the level attained during the war.

The trees which yield gum myrrh grow wild in various portions of British Somaliland, particularly in the territory of Ogaden, which produces the best. Smaller quantities of gum myrrh are produced in Arabia, as well as in Abyssinia. About a year and a half ago, writes the United States Consul at Aden, experts in growing gums made their way into sections of Arabia, near Katabba, where most of the gum trees abound, and it is reported that they are greatly improving the yield of the gum trees.

The following table shows the trade of Aden in gum myrrh:—

Countries of origin and destination.	1913-14	1918-19	1919-20	1920-21
Imports from—	Cwt.	Cwt.	Cwt.	Cwt.

GENERAL NOTES.

BENJAMIN WARD RICHARDSON MEMORIAL LECTURE.—Sir William Collins will deliver the Benjamin Ward Richardson Memorial Lecture at the Barnes Hall of the Royal Society of Medicine, on Thursday, October 12th, at 5 p.m. Admission to the meeting is free and

cards may be obtained from the Rev. George Martin, St. John's Vicarage, Kilburn. The lecture is given under the auspices of the Model Abattoir Society, which was founded in 1886 by Sir Benjamin Richardson, with the object of abolishing the private slaughter-house system, and making compulsory the adoption of the most rapid and humane methods of slaughtering animals.

PORTLAND CEMENT AS A FIRE EXTINGUISHER.

A report from the Chief Officer of the Seneca Fire Brigade, U.S.A., draws attention to the remarkable efficiency of Portland cement in extinguishing fire. In the course of a fire which started in a general store and extended to an adjacent timber yard, the use of cement, of which there was plenty at hand, was suggested, and it was employed partly by scattering the material dry over stacks of timber in immediate danger and immediately wetted by the fire brigade, and partly in the form of thin grout thrown upon blazing timber. The effects were prompt and astonishing, the spread of the fire being almost instantly checked. The flames from timber already burning began to abate and within 1½ hour the fire was extinguished. The cement grout thrown upon the blazing wood is said to have had a threefold effect (1) It acted similarly to dry powder chemicals, reducing the fire quickly and more efficiently than chemical powder as it acted in spite of the fact that the fire was in open air. (2) It almost entirely stopped the flying of sparks and tinder. (3) It caked over the fire, smothering it and shutting out air, so that combustion could not take place. An interesting use of cement in the store building was in extinguishing the blaze from a 400-gallon tank of oil into which tinned goods had fallen and were constantly exploding, throwing blazing oil about the building. The flames were finally extinguished by throwing sacks of dry cement into the tank. The report states that by the employment of cement a fire was stopped that would otherwise have entirely destroyed the timber yard.

OLIVE OIL PRODUCTION IN ITALY.—The production of olive oil in Italy averaged 1,884,000 hectolitres (49,771,000 gallons) a year for the 1909-1920 period, according to figures issued by the Italian Ministry of Agriculture. The maximum output in one year was 2,890,000 hectolitres (76,347,000 gallons) in 1918 and the minimum was 958,000 hectolitres (25,308,000 gallons) in 1912. These figures, points out the United States Consul at Leghorn, refer only to the product of the first and second pressings. The sulphur oil and washed oil are additional and amount to about 500,000 hectolitres (13,209,000 gallons) annually. The average yearly crop of olives for the 12-year period was 1,140,600 metric tons.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.*

THE MECHANICAL DESIGN OF SCIENTIFIC INSTRUMENTS.

By PROFESSOR ALAN F. C. POLLARD,
A.M.I.E.E., F.Inst.P.

LECTURE II.—*Delivered February 27th, 1922.*

We have now seen that by suitable application of five degrees of constraint, we can simulate the turning and sliding pairs of mechanism in a surprisingly simple manner. We cannot do this, however, with the screw pair—the third and most complicated pair of the three unique lower pairs of mechanism. The screw pair is a degree of constraint of the most general character and cannot be produced by constraining one point of the body to a curve surface.

For it consists in preventing one line of the body from longitudinal motion, unless accompanied by rotation round this line in fixed proportion to the longitudinal translation, leaving every other motion free.

The other free motions are two rotations about axes perpendicular to this line and two translations perpendicular to the same line. That is four degrees of freedom which, with the degree of freedom to screw and the one degree of constraint, make up the six elements.

The screw pair is possibly the most remarkable of all the ingenious mechanical inventions of man, and it is the most troublesome to manufacture. The Whitworth thread, for example, has seven elements, error on any one of which may be sufficient to cause a gauge to reject work which ought to pass or *vice versa*. These seven elements are

1. The full diameter or the overall diameter of the screw.

2. The Core diameter or the diameter at the root of the thread.
3. The Effective diameter.
4. Pitch.
5. Angle.
6. Radius at crest.
7. Radius at root.

An immense amount of work was done during the war on the production of the screw pair. But in spite of the ingenious methods which have been introduced for its accurate production and the delicate means which have been devised for checking the various errors to which it is liable, it is impossible to manufacture the screw pair with the same degree of precision as the turning and sliding pairs.

During the war many thousands of a certain gun clinometer* were required. An important part of this clinometer consisted of a double threaded screw about 5 inches long and 0.1 inch pitch, and a nut which was required to move from end to end of the screw without any variation of fit. The specification for its manufacture was exacting to a degree.

The nut as specified by the authorities, was fitted with three plungers P, Fig. 13, pressed against the screw spindle by three springs S, which were supposed to take up variations of fit and shake. This unsound design was doomed to failure, and after short use in the field, the nut worked loose.

A satisfactory nut was designed by the Cambridge and Paul Instrument Co.

There are 4 degrees of freedom; there must, therefore, be 4 parts of the nut upon which the screw spindle can bear.

These four parts are shown in part section in the figure and the single plunger P is the source of the pressure to ensure contact upon the 4 surfaces.

Since there must necessarily be generous allowances between a screw and its nut for the purposes of manufacture, there must be back lash.

**Trans. Optical Soc. Vol. xxii., p. 49.*

FIG. 13.

This back lash is a troublesome and undesirable evil and generally speaking in measuring instruments in which the screw is used as one of the metric elements, it must be overcome, or its range must be capable of exact measurement.

The back lash can be eliminated by keeping the screw and its nut in contact with the helical surface of the thread by pressure applied in the line of the axis.

This was done most simply and effectively by Sir Joseph Whitworth* in the design of his famous Millionth measuring machine, which is the forerunner to all modern measuring machines.

Thus by tightening these screws, the square thread on the screw spindle can be pinched to any extent desirable and all back lash removed.

The tangent screw engaging with the worm wheel H of the metric screw spindle is also made in two halves, upon the same principle as the divided nut and is made to press both sides of the teeth of the screw wheel, just as the nut is adjusted to press both sides of the square thread. Sir Joseph Whitworth stated that he sometimes found the back lash to lie within two-millionths of an inch, with this arrangement.

FIG. 14.

The nuts with which the carefully made square threaded metric screws engage are each split into two halves, as shown in Fig. 14. One half is forced into one end of the sliding block B or C, which carries the measuring anvil at its other end, and the other half of the nut is prevented from turning and is pressed inwards by four screws in the sliding block, two of which are shown in the section.

A modification of Sir Joseph Whitworth's design is one in which the secondary nut is prevented from turning and is pressed away from the primary nut by an intervening spring. Since the two nuts are upon the same screw the distance between them remains constant during rotation of the screw spindle and thus the axial pressure distributed over the threads of the spindle and its nut does not vary. This arrangement was used by Kelvin in the micrometer screws of his electrometers.

*The Whitworth Measuring Machine by T. M. Gooden, and C. P. B. Shelley. 1877.

In delicate measuring instruments this constancy of pressure is necessary.

FIG. 15.

In a device invented by Grubb in 1886 for the declination slow motion of telescopes, shown in section Fig. 15, A, B, C, D is a portion of the arms attached to telescope or cradle, and E, F, G is the clamp arm. The screw has a bearing *b* with spherical seating on the telescope arms and its spherical nut *n* bears in the bearing G of the clamp arm. A short stiff spring S is attached to this clamp arm, bearing not directly against any part of the other arm, but against the end of a second screw of the same pitch as the main screw, the nut of which is a pinion *oo* engaging with a similar pinion *pp* keyed to the main screw. The point of this second screw, therefore, advances as much in one direction as the frame A, B, C, D is carried in the other, when the milled head is turned and consequently the point of the screw does not sensibly vary in its position with respect to the clamp arm E, F, G. In this way a short stiff spring brings a constant pressure to bear between the screw and its nut.

A common way of eliminating back lash between screw spindle and nut is to split the nut longitudinally so that it can be clamped with suitable pressure upon the screw. Such an arrangement is found in the fine adjustment of the large Zeiss photomicrographic microscope stand which has been pronounced by some people to be so perfect in its action.

This method, however, must be used with considerable caution, for the roots and crests of the components may be forced into contact unless the thread is very carefully made. If contact between the roots and crests takes place to the exclusion of contact between the helical surfaces of the thread, rapid wear takes place and erratic relative

motion of the screw and its nut soon develops.

The nut of the screw spindle of the Fabry and Perot interferometers is split and clamped. But the thread has been specially designed.

The crests and roots are made to clear one another, and when the nut is clamped the pressure is taken by the helical surfaces of the threads only.

If the standard Whitworth form of thread is used the clearance of roots and crests, it has been found, gives too small a bearing on the helical surface of the thread. Consequently the thread has been re-designed and an angle of 47° has been given to the thread instead of the standard 55° angle of Whitworth. In this way sufficient bearing surface is ensured.

The fine adjustments of microscopes are in the majority of instruments either screw or lever devices, designed to magnify the movement of the optical system at the milled head of the adjustment.

The function of the fine adjustment in high class research instruments should be chiefly metric and should be used as sparingly as possible merely for the purpose of focussing.

It is essential then, in this case, that the velocity ratio of the mechanism should be constant, that is to say, no matter what the position of the milled head, a unit turn of it should move the optical system through the same distance.

Generally speaking, this is not possible with a system of levers, and, further, they are liable to rapid wear, and to develop variable contact, which alters their ratio and introduces unsuspected error.

There is a form of screw mechanism peculiarly adaptable to the fine adjustment of microscopes which I wish to bring before your notice. It is the so called Campbell differential screw, said to have been originally invented by White for other purposes.

Two screws, S and T, of different pitches, are cut on the same spindle. (See Fig. 16.) The first screw engages with a nut fixed to the limb of the instrument, while the second screw engages with a nut H fixed to the tube carrying the optical system. A single rotation of the milled head D advances the screw and carries the tube with it through a distance equal to its pitch, but during this rotation, the second screw causes its nut and hence the tube, to advance in the opposite direction, through a distance equal to its pitch.

FIG. 16.

So that, during one rotation of the milled head, the tube advances a distance equal to the difference of the pitches of the two screws, whilst the milled head itself advances a distance equal to the pitch of the first screw.

Thus, if the two screws have 30 and 31 threads to the inch respectively, one turn of the milled head advances the optical system through $1/930$ of an inch, whilst the milled head itself moves through $1/30$ " axially. Thus a delicate and minute movement is accurately given to the tube by means of two screws of coarse pitch and robust construction. Further, if a vertical scale is placed against the edge of the milled head, its unit representing one turn of the head, is $1/30$ " long.

Thus, $1/30$ " on the scale represents a movement of $1/930$ " of the optical system.

If the spindle has 20 and 25 threads cut upon it, then the movement of the tube corresponding to unit turn of milled head is $1/100$ ". Almost any desired velocity ratio can be obtained, and, moreover, the device is a strictly metric one, for the velocity ratio is constant throughout the whole working range.

Why this almost perfect adjustment for microscopes has gone out of fashion I am at a loss to understand.

As a rule, the screw spindle of these Campbell differential movements is far too small in diameter, and certainly should not be less than that of the screw spindle of the ordinary shop micrometer to withstand wear satisfactorily. This may account for the unpopularity of this fine adjustment.

(The lecturer showed a microscope kindly lent and made by Messrs. Swift, with this differential screw fine adjustment, which

was 20 years old, and at the end of the lecture the perfect focussing of a $1/12$ " oil immersion was demonstrated.)

Frequently, the success of measuring instruments depends upon the manner in which the nut or screw spindle is connected to the moving piece of the instrument, or the manner in which the screw spindle is restrained from end long motion.

It is essential that no indeterminate strains should be set up between the screw and its nuts, or that the screw spindle should not oscillate axially during its rotation.

An excellent design obviating possible strain between screw and nut, is shown in the feed screw mechanism of the rocking microtome of the Cambridge and Paul Instrument Co. The movement of this nut determines the thickness of the section cut, and this must be constant throughout the range of working.

FIG. 17.

The screw, S, Fig. 17, works in a nut N, on which the lever rests at its ring-shaped end, shown in section at C. Two V grooves are formed in the ring shaped end C and the nut has wings which engage with those grooves. It is thus prevented from turning and yet can take up a position of repose on the screw spindle.

In other cases the end of the screw spindle bears against the moving piece and the axial movement of the screw spindle has to be accurately communicated to the moving piece.

A simple arrangement to ensure contact between the end of the screw and the piece to be moved is to close the kinematic chain by a constant force closure in the form of a "C" spring as shown in Fig. 18.

This simple and effective arrangement is due to Sir Horace Darwin, but though constant pressure is brought to bear

FIG. 18.

axially between the two pieces and consequently they cannot be subjected to lateral strains, it does not do away with back lash.

If, however, the end of the screw is not precisely a surface of revolution about the axis of the screw spindle, its point of contact will describe a small circle on the bearing surface of the moving piece, and if this surface is not exactly square to the axis a periodic error will develop between the screw and the piece. In addition to this, unnecessary strain may be set up between the pieces.

The manner in which these defects may be overcome is shown in the mechanism of the Cambridge and Paul Instrument Co.'s reading microscope, and also in the substage screw adjustment of the Keith Lucas microscope with geometrical slides, already referred to.

In the reading microscope, a section of

arrangement it is necessary, of course, that the rod shall always be pressed against the end of the micrometer screw with a constant pressure. The long spring S attached to the frame at the right hand end and to the end of the tube on the left, performs the double duty of maintaining the necessary pressure against the micrometer screw and eliminating back lash between the latter and its nut, and is sufficiently long to maintain a fairly constant pressure over the working distance of the screw. (*The lecturer here showed the instrument.*)

Such an arrangement as this, however, would be unsatisfactory for such an instrument as the Fabry and Perot interferometer, where accurate movements within less than $1/10$ th of a wave length of light, i.e., within a fraction of $1/20,000$ mm. on the average, are necessary.

In this instrument the arrangement of coating parts to obviate the possible oscillation of the screw spindle is very beautiful. The thrust of the spindle is taken up by a quartz plate, which bears against a small and highly polished area on the end of the spindle, which is produced before the spindle is unchucked from the lathe in which it is made. The area is thus dead square to the axis of revolution.

FIG. 19.

which is shown in Fig. 19, the micrometer screw M is connected to the hollow rod A (to which the travelling microscope is clamped) by the small steel link or rod W, the pointed ends of which are seated in countersinks in the two pieces. With this

If now the point of contact of the spindle and quartz plate be observed through the latter, interference bands will be seen. If the quartz plate is not dead square to the axis of revolution these bands will shift during a turn of the spindle.

The quartz plate can then be adjusted until no such shift takes place.

So that in this way the point where the geometric axis of revolution of the screw spindle cuts the plane of the quartz plate can actually be seen and perfect adjustment secured. (*The lecturer here showed the instrument.*)

In all gearing in which teeth engage with one another by sliding and rolling contact back lash is very troublesome when accuracy is required.

A very ingenious arrangement for overcoming this difficulty in the case of bevel gears is shown in an excellently designed mass production refractometer of Messrs. Bellingham and Stanley, patented by Mr. W. Taylor.

FIG. 20.

Vertical and horizontal sections through the parts which are of interest, are shown in Fig. 20.

It is necessary that the two compound prisms used for the compensation and measurement of dispersion, and housed in the two sleeves h^1 h^2 , be capable of measured rotation in opposite directions without

loss of motion in either sense. To secure the opposite rotations the inner ends of the sleeves are formed as crown gears h_3 and h_4 , which are engaged and connected by two bevel pinions h_5 rotating freely on studs h_6 fixed on the opposite sides of a ring h_7 . To eliminate backlash this ring is permitted a small amount of play transverse to the optic axis of the tube and can be clamped in such a position by the screws j^1 j^2 and j , that the bevel pinions bear equally upon the crown gears.

Another device to obviate back lash between two pieces, which I cannot refrain from describing, is the ingenious one of Mr. William Taylor to prevent back lash between the index plate of a dividing head and its face plate. The index plate is centred by fitting closely and squarely up to a shoulder on the plain cylindrical extension or hub of the dividing head face plate, to which it is secured by the taper pins projecting from the face of a split collar.

FIG. 21.

These pins engage in holes in the index plate. The two holes in the index plate are on one straight line through the centre of the plate, but the pins in the collar are placed to engage the holes of the plate, both on one side towards the slit in the collar, as shown in Fig. 21.

In use, the index plate is pushed on to the hub and is followed and pressed up to the shoulder by the split collar. The pins engaging in the holes force the index plate into contact with the hub and thus prevent all back lash.

Tightening the collar then further tends to jam the index plate. It will be observed that this is an essentially manufacturing

proposition for not only is the alignment of holes and pins avoided, which alignment would be very troublesome in manufacture, but the back lash unavoidably attendant upon such alignment is entirely got rid of.

The design is geometrical for it will be seen that the index plate has three surfaces of constraint to prevent its movement relative to the face plate in its own plane, one on each pin and one on the hub.

Before leaving the screw pair the troublesome crossing of screw threads when engaging two screw members of large diameter and small pitch and means of avoiding the trouble, may be mentioned.

If one member is provided with a cylindrical "pilot" by turning away a few threads to the root or core diameter the co-axial relation of the two parts is secured by the crests of one member engaging with the "pilot" of the other before the threads engage.

Another way, due to Mr. William Taylor, is to mill away the tapering portion at the commencement of the thread in both members. Then by marking on the flanges the part of the circumference where the abrupt threads commence no difficulty will be found in trying to engage them.

If the threads are milled, the abrupt thread may be produced by a suitable cutter without adding to the cost of the operation.

This abrupt thread is specially useful for the mounts of lenses in optical instruments. (*The lecturer here showed samples of lens mounts.*)

In cases, however, where several lens mounts are assembled in a tube and require to be changed frequently for cleaning or for the purpose of quickly changing the optical system, a most ingenious method has been invented by Mr. William Taylor, which reduces the cost of production.

The lens is mounted in a short cylindrical cell the outside diameter of which is slightly less than the outside diameter of the tube it has to fit.

A little more than half this circumference is milled away to a radius equal to that of the inside of the tube.

The tube itself has a slot milled across it nearly to the diametral plane of the tube, and of a width equal to the height of the mount. The mount will then snap into the tube.

These are seen in Fig. 22, where the microscope tube of a "Talyden" is shown

with the lense mounts assembled. and also just engaging with the milled slots in the tube ready to snap into place.

FIG. 22.

Let us now return to the geometrical slide. We have seen that by causing the part of an instrument to have contact at five points on five suitably chosen surfaces, we not only constrain it to move with one degree of freedom, but we allow it to take up a position of repose, and none of its parts are subjected to unnecessary strain.

If, therefore, we merely require that the body shall have no rotations about the two horizontal axes, and be constrained in one of its translations only, we can remove two more surfaces and allow the body to rest on three. Thus we see that a rigid body will rest by three points on an uneven fixed surface in a state of repose, without unnecessary strain. If, however, the body is heavy, and no longer rigid, it will bend between the points of support in virtue of its own weight, and this is the necessary and unavoidable strain to which it will be subjected.

This bending for a given elastic body will be greater the greater the distance between the supports, and the question at once arises whether it is possible to extend the principle of a three point support to several points distributed over the under surface of the body so as to reduce the flexure between the points of support produced by gravity. It is at once evident that, provided we do not fix any of the subsidiary points of support, and limit the fixed surfaces to three, we shall leave the body free to take up its position of repose.

Thus, if we support the body at nine points by means of three frameworks, each with three bearings and each framework at one point on each of three fixed

bearings, the body will rest in a state of repose.

This process can be pushed to any extent, and the body can be supported at any number of points in a state of repose.

It will be instructive to examine for a moment the way in which Lord Rosse* supported the six foot speculum of his giant telescope which weighed over three tons. He says:—

“The cast iron carriage carries three ball and socket joints, directly under the centre of gravity of three equal sectors, into which the speculum may be supposed to be divided (as shown at A, B and C, Fig. 23.) The centre of the ball is in the

FIG. 23.

centre of gravity of the triangle (shown isolated in Sector A), not merely as respects its plane, but thickness also. These three triangles which we call primary, carry at their angles, by ball and socket joints, nine secondary triangles (shown in Sector B), supported at their respective centres of gravity; and they, in a similar way, carry twenty-seven tertiary triangles (shown in sector C) each carrying three gun metal balls of $1\frac{1}{2}$ inch diameter—in all, eighty-one balls, which support twenty-seven equal portions of the speculum. Between the balls and the speculum, twenty-seven thin brass plates are interposed, attached to the speculum by pitched cloth, not so much with a view of giving support between the balls, which would probably be quite unnecessary, but to make a smooth surface for the balls to roll upon without grinding the back of the speculum true.”

The iron polishing tool weighing over one ton, is suspended by thirty-six points in a manner similar to the support of the mirror, and is shown suspended in Fig. 24.

“As soon as the tool is prepared, the gimbels are removed; and it is then managed by the shackle in the centre.

FIG. 24.

The shackle carries a triangle with a lever at each angle. Each lever carries similarly two levers, connected at their extremities with T shaped levers, which carry the tool by thirty-six points. The chain through which the counterpoise acts during the progress of grinding and polishing, is hooked to the shackle and the strain is thus distributed so equally that there is no sensible distortion.”

This system of vertical support to the speculum of Lord Rosse is in principle the same as that applied by Grubb in 1834 to a 15 inch speculum constructed for the Armagh Observatory.

If we turn to Grubb's arrangement of

FIG. 25.

the points of support for the four foot speculum of the Great Melbourne Telescope*, we shall find that it is similar to Lord Rosse's except that Grubb managed to pack the levers into a smaller space vertically.

The speculum is supposed to be divided into 48 portions of equal weight. See Fig. 25.

These portions are supported by the 48 points of 12 triangular levers, and six straight levers, shown at C, Fig. 26. The centres of these 18 tertiary levers are supported by six triangular secondary levers, two of which are shown at B.

FIG. 26.

The centres of these six secondary levers are supported by the three primary straight levers, one of which is shown at A. Finally, the centres of these three primary levers are supported on three fixed surfaces of the frame.

FIG. 27.

Fig. 27 shows the final arrangement of

all the levers on the under side of the great mirror.

FIG. 28.

Fig. 28 shows the polishing machine with the mirror and polishing tool in position, and it will be observed that the support of the tool to prevent flexure is similar to that adopted by Rosse.

FIG. 29.

Figure 29 shows Lassell's* method of supporting large specula. The sector of 120° is divided up into six equal areas, and thus the whole speculum into 18 equal portions.

The circles represent discs of brass bearing against the back, the centres of which coincide with the centre mass of the elementary areas into which the speculum is supposed to be divided. Pairs are connected by short levers at each end of which is a hole loosely fitting pins projecting from the discs. The under surface of the discs are small segments of spheres. The centres of these levers are again supported by the ends of a triangular lever MNO, in the same manner as the discs are supported by the first three levers.

Finally, the point P of this lever is supported on a screw or stud fixed in the end plate of the telescope tube. The point

**Roy. Soc. Phil. Trans.* Vol. 159, 1869, p. 127.

**B.A. Report*, 1850, Edinburgh, p. 181.

P is the centroid of the loads at MNO, and, therefore, $PM=2 PQ$. Thus, the mirror is ultimately supported on three points.

Lassell finds that the mirror is distorted with change of temperature, and rightly assigns this defect to differential expansion between the iron of the levers and the speculum metal and to the fixation of the various points of support. This defect, he states, he has to some extent removed by making the surfaces of contact of the discs as smooth as possible. To remove the defect entirely he proposes to make the metal of the levers of an alloy described by Lord Rosse, which has sensibly the same expansion as the speculum metal itself.

In the 72" reflecting telescope at Observatory Hill, Victoria, Columbia, of which the mounting is made by the Warner and Swasey Co., of Cleveland, Ohio, the mirror has an aperture of 72" with a focal length of 30 feet and is used either with a Newtonian flat or with a Cassegrain mirror.

This huge mirror is so thick that it is only necessary to support it on nine counter-balanced pads arranged in groups of three, and it is stated that it nowhere departs from the correct parabolic figure by more than an eighth of a wave length of light.

In many instruments there is a moving part which acts as an indicator, and the position or motion of the indicator allows us to deduce some conclusions with respect to the force that acts upon it. This force will be the quantity we desire to measure, but friction is always present between the co-acting parts and reduces the accuracy of our observations.

If the magnitude and direction of the resisting force of friction were always known, it would be of no consequence.

But the magnitude of friction is liable to sudden alterations owing to causes which we can often neither suspect nor detect, so that the only way in which we can make any approach to accuracy is by diminishing as much as possible the effect of friction.

Nevertheless, in sensitive instruments, however much it may be diminished friction introduces an error which we shall discuss later on.

Whenever there is "sliding or rolling contact there is friction, but if it is possible to make the extent of the sliding or rolling small compared with the movement of the indicating part, we may reduce the effect of friction to a very small part of the whole effect.

An example of this which appears to have been forgotten is Joule's method of mounting the needle of a dip circle.* The axis of the needle, instead of rolling on agate planes, is slung on two filaments of silk, the ends of the filaments being attached to the arms of a delicate balance.

In order that the needle may be in neutral equilibrium as it rolls upon the filaments, its centre of mass must neither rise nor fall.

To secure this condition, it is only necessary that the arms of the balance are equal and the filaments are at right angles to them.

Like friction, the elastic force of torsion of a filament, though much more regular, is liable to alterations arising from known, as well as unknown, causes, and depending largely upon its previous history.

Hence it is sometimes better to employ a mode of suspension in which the force of restitution depends upon the weight of the suspended parts rather than upon the elastic torsion.

Such a suspension is the well-known bifilar suspension, invented by Gauss and Weber for their magnetic instruments, and afterwards used by Baily in his experiments on the attraction of masses. The suspended body is in equilibrium, and its centre of mass is in the lowest position when the two filaments are in the same vertical plane. When the body is turned about a vertical axis, its centre of mass is raised since the filaments remain constant in length, but move out of the vertical plane. Gravity, therefore, brings the body back to zero position, and this force is very regular in its action, and more reliable than the elastic force of torsion.

In turning pairs the friction may be reduced by reducing the size of the axle and by supporting it on friction wheels or by reducing the area of contact to that of a point bearing in a pivot cap or jewel, or by reducing the area of contact by means of hardened balls placed between the axle and its bearing.

In cases where the movement of rotation is small, the friction can be still further reduced by the use of knife edges.

In balances and other lever systems the bearing of the lever is in the form of a knife edge which rests on a plane.

No matter how carefully a knife edge is made, its physical edge is in reality cylindrical

Electricity and Magnetism, by Clerk Maxwell. 3rd ed. Vol. II., p. 125.

so that the friction is due to the rolling of a cylinder of small radius upon a plane.

Thus in all measuring instruments which make use of lever systems with knife edges, and are dependent for their accuracy upon the ratios of the arms of the levers, besides the error due to friction, there is error due to the shifting of the point of contact as rolling proceeds, though frequently this error is so small that it does not sensibly alter the ratio of the lever arms. In delicate mechanisms, it introduces a form of variance which we shall discuss later. In addition to this, the radius of the rolling cylindrical edge increases with wear, which is a very undesirable feature. Nevertheless, knife edges are the best means at our disposal in our attempts to secure small rotations about a definite axis with minimum friction, when the load is not excessive.

Since a knife edge can slip about on its supporting plane, and rotate about the vertical as well as about its edge, it has four degrees of freedom. It requires, therefore, only two surfaces of constraint and can in some cases be replaced by the contact of two steel balls rigidly connected together bearing on a plane. Such a knife edge is useful when the radius of the rolling edge is required to be accurately known. In some devices, however, the radius of the rolling edge is required to be known and to be so small that it cannot be constructed.

There is a very beautiful little instrument --The Talymin--which illustrates this remark. The design of this instrument is by Mr. William Taylor, and it is constructed by Messrs. Taylor, Taylor and Hobson.

The instrument is a comparator and is used for the purpose of checking the dimensions of manufactured parts accurately and quickly to the $1/10,000''$.

Consider a cylinder of small radius, r Fig. 30, which has rolled a distance x on a plane. If a pointer is attached to the cylinder, the pointer of length l will move over a scale distance c .

Consequently since $r/x = l/c$,
If $x = .0001''$, $l = 4''$ and $c = .04''$. $r = .01''$.

It would be quite impossible to make a roller of $.02''$ in diameter.

This difficulty has been overcome by Mr. Taylor in this way.

Two coaxial cylinders of radii r_1 and r_2 are turned out of the same rod.

Round them are wrapped two bands B_1 and B_2 respectively secured to the cylindrical portions of radii r_1 and r_2 . The

FIG. 30.

band B_2 is connected to the plunger at the end of which is the measuring anvil. This plunger is pulled by a spring in the direction of the arrow and also in the opposite direction by the weaker spring S .

The smaller cylinder rolls upon the plane PQ to which the band B_1 is secured.

If the cylinders roll through an angle ϕ indicated by the pointer attached to them, the band B_2 moves through a distance $r_2\phi$, but in so doing the cylinder r_1 rolls on the plane and so carries the band B_2 through a distance $r_1\phi$ in the opposite direction.

So that the total movement of the band is $(r_2 - r_1)\phi$.

Now the difference $r_2 - r_1$ can be made as small as one pleases and thus a minute movement of the band is indicated by a large movement of the pointer.

In the actual instrument the plane PQ is inclined so that the tension of the bands keeps the roller in contact with it and this modification introduces a correction in the simple formula which is of no consequence for it can be definitely calculated.

The Air Ministry are having considerable trouble with their altimeters, which are nothing but aneroids that measure the altitude by decrease of the pressure of the atmosphere. In these aneroids the pressure is indicated by the movements of a diaphragm which will not recover quickly when the aeroplane is rapidly descending. This is due to a certain elastic drift caused by overstrain of the diaphragm, which might be considerably reduced by making it stiffer and eliminating the corrugations which are the seat of overstrain with correspondingly smaller movement for a given variation of pressure. But this movement of the

diaphragm would be so small that the present arrangement of the coating parts in the instrument would not give an open scale easily read.

The application of Mr. Taylor's invention to this instrument might get over all the difficulties which at present make it an unreliable instrument.

In some applications of the knife edge it is necessary to impose upon it two more degrees of constraint, so that it may have but two degrees of freedom left, *i.e.*, a rotation about its edge and a motion of translation in the direction of its edge.

The latter freedom can be limited to small excursions by suitable stops, which during rotation of the edge are held free of it.

The knife edge must then bear against four surfaces.

A geometrical design of such a knife edge is shown in Fig. 31, and is incorporated in the rocking microtome of the Cambridge and Paul Instrument Co.

FIG. 31.

The knife edge is formed by three prisms of rectangular section connected together so that the three lower and inner edges are contiguous. The single edge thus formed bears on four planes sloping at 45° to the horizontal, as shown in the figure — the portion of it which is part of the central prism bears on the two inner sloping planes and the portion formed by the two outer prisms bears on the outer planes sloping at 90° to the former. Thus the compound prismatic piece turns about a single 90° and, therefore, robust edge, which is seated in what is virtually a 90° "V" groove.

In this design it is evident that if the knife edge bends owing to excess of load, the two outermost edges will leave their planes and the geometrical relations will be sacrificed.

This deficiency is ingeniously overcome in the arrangement shown in Fig. 32.

FIG. 32.

Here the knife bearing planes are capable of rotation about axes perpendicular to the direction of the knife edge. So that when the knife edge bends the planes rotate and maintain line contact with the edge. Such an arrangement should be of value in heavy weight measuring machines, such as locomotive beams.

These two beautiful geometrical designs are due to Sir Horace Darwin.*

So far we have discussed in detail various devices which will reduce the aberrations in the geometrical relations of the coating parts of an instrument to a minimum. It now remains for us to see how the various imperfections due to friction, back lash and want of true elasticity, etc., affect the indications of the instrument in relation to the measured quantity.

**Scientific Instruments, their Design and Use in Aeronautics*, by Horace Darwin, M.A., F.R.S. *Aeronautical Journal*, July, 1913.

NOTES ON BOOKS.

ARGONAUTS OF THE WESTERN PACIFIC. By Bronislaw Malinowski, Ph.D. (Cracow), D.Sc. (London). With a Preface by Sir James George Frazer, F.B.A., F.R.S. London: George Routledge & Sons, Ltd. 21s. net.

This volume forms part of the excellent series of monographs by writers connected with the London School of Economics and Political Science, and gives an extraordinarily interesting account of the social life and institutions of a group of islands of which the very name is hardly known to the ordinary reader. In 1914 the author was awarded the Robert Mond Travelling Scholarship, which, with some other assistance, enabled him to devote the period 1914-20 to ethnographical research. After spending six months among the natives of Mailu in New Guinea, he pro-

ceeded to the Trobriand Islands, to the east of New Guinea, where he spent about two years, living amongst the inhabitants as one of themselves, conversing with them in their own tongue, and gaining a remarkable insight into their institutions and methods of thought. The present volume gives the results of his observations, and, illustrated as it is by numerous photographs and maps, it is a remarkable contribution to the study of primitive sociology.

Perhaps the most interesting and novel feature in the book is Dr. Malinowski's account of the institution known as *Kula*. This is a form of exchange of extensive, inter-tribal character, carried on by communities inhabiting a wide ring of islands, which form a closed circuit. "Along this route articles of two kinds, and these two kinds only, are constantly travelling in opposite directions. In the direction of the hands of a clock moves constantly one of these kinds—long necklaces of red shell. In the opposite direction moves the other kind—bracelets of white shell. Each of these articles, as it travels in its own direction on the closed circuit, meets on its way articles of the other class, and is constantly being exchanged for them. Every movement of the *Kula* articles, every detail of the transactions is fixed and regulated by a set of traditional rules and conventions, and some acts of the *Kula* are accompanied by an elaborate magical ritual and public ceremonies."

In every island within the circuit a certain number of men take part in the *Kula*. They receive the goods, hold them for a short time and then exchange them. Associated with this ceremonial the natives carry on ordinary trade, bartering from one island to another a great number of goods, often unprocurable in the district into which they are imported, and indispensable there. Thus the *Kula* is an extremely big and important institution: it involves the building of a large number of sea-going canoes, it welds together a large number of tribes, "and it embraces a vast complex of activities, interconnected, and playing into one another, so as to form one organic whole."

Dr. Malinowski's full account of this remarkable institution throws a fresh light on the old Jeremy Bentham conception of Primitive Economic Man. *Kula*, as Sir James Frazer remarks, "is not based on a simple calculation of utility, of profit and loss, but it satisfies emotional and æsthetic needs of a higher order than mere gratification of animal wants." It would indeed seem to be Primitive Economic Man's substitute for the circulating department of the Victoria and Albert Museum! "The trade in useful objects, which forms part of the *Kula* system," Sir James continues, "is in the minds of the natives entirely subordinate in importance to the exchange of other objects, which serve no utilitarian purpose whatever. In its combin-

ation of commercial enterprise, social organisation, mythical background, and magical ritual, to say nothing of the wide geographical range of its operations, this singular institution appears to have no exact parallel in the existing anthropological record; but its discoverer, Dr. Malinowski, may very well be right in surmising that it is probably a type of institutions of which analogous, if not precisely similar, instances will hereafter be brought to light by further research among savage and barbarous peoples."

INTERNATIONAL AIR CONGRESS, LONDON, 1923.

Following on the Congrès International de la Navigation Aérienne held in Paris in November, 1921, it is proposed to hold a similar congress in London towards the end of June next year. Group Captain the Duke of York, has consented to become President of the General Council of the Congress, and Lord Weir of Eastwood, has accepted an invitation to become a Vice-President. A strong organising committee representative of all phases of British aeronautical activity, including the Air Ministry, has been formed, with the Duke of Sutherland as Chairman.

The Congress will be open to all countries which are signatories of the International Air Convention, or are represented on the Fédération Aéronautique Internationale; individual invitations being issued through national committees in process of formation in each country. Membership will be divided into two classes: (a) Ordinary Members, and (b) Associate Members, comprising the families of ordinary members, at a subscription of £1 and 10/- respectively.

According to present arrangements the Congress will occupy one week during the last fortnight in June, 1923, the reading of papers alternating with visits to various aircraft factories and establishments. It is hoped that the Air Ministry will be able to arrange for the Royal Air Force Pageant to take place on the Saturday of the Congress week and that the Royal Aero Club may organise a race meeting on the Tuesday or Thursday. Monday, Wednesday and Friday will be devoted to the reading of papers, and discussions thereon, which will be divided into four or more main groups or sections holding simultaneous sessions in different rooms.

As the time available for the reading of papers will be limited, a "reading committee" is to be formed, though it is hoped to arrange that the official report of the Congress to be published later shall contain a wider selection of the papers sent in. An official reception will be held in the evening of the Monday of the Congress week and the proceedings will be closed by an official banquet on the Saturday.

It is important that the Congress should not be confused with the British Air Conference called each year by the Air Ministry. The latter is of a domestic nature dealing with aeronautical matters so far as the British Empire is concerned. The Congress, on the other hand, is essentially international in character and is intended to be one of a series to be held in various countries at which experts may meet to discuss the technical and scientific development of aeronautics in all its aspects.

MOTHER OF PEARL INDUSTRY IN BETHLEHEM.

Bethlehem, in Palestine, is the centre of a mother-of-pearl industry which supplies beads, rosaries, inlaid work, carvings, and miscellaneous ornaments to all parts of the world. This industry is one of the most important of the few that exist in the Holy Land.

Of the rosaries made in Bethlehem from mother-of-pearl beads, combined with silver or white-metal chains and wire, about one-third of the total product is exported to North and South America and the remainder goes principally to European countries of which, before the war, Austria and Germany received particularly large quantities. During the year 1913, writes the United States Consul at Jerusalem, there was invoiced at the American consulate in Jerusalem for shipment to the United States, \$19,207 worth of Bethlehem mother-of-pearl rosaries of the first and second class qualities. For the calendar year 1920, the total value invoiced amounted to \$31,846. Only shipments valued at \$100 or more require consular invoices, and it is probable that during these two years there were as many rosaries and beads taken or sent to the United States in small quantities as were invoiced at the consulate.

The long strings of beads known as necklaces are not so important in the export trade as are the rosaries. A great many necklaces are sold to tourists by local curio shops. Considerable quantities of tiny beads are made and sold in strings or bunches to be used for various trimming purposes. These beads are in demand by the Moslem women of northern Africa, particularly in the Algerian markets, which are supplied by French dealers where they are used as trimming for articles of clothing. Beads of various sizes, usually in the round form, are made into small strings of "play" beads. A great many beads in this form are sold to Moslems and certain classes of Levantine Christians. Amber, glass, and other materials are used for these "play" beads, but the use of mother-of-pearl for the purpose is increasing.

The refuse, broken pieces, and butt ends of mother-of-pearl shells, used by button factories, supply most of the raw material used in the Bethlehem bead and rosary industry. For the larger carved pieces and other pieces requiring whole or nearly whole shells, the raw material

is obtained directly from the Red Sea, India and Australia, but the imports of this class of raw material are not large.

The waste from the button factories is imported in quantities estimated at about 20 tons per month. Most of this waste is obtained from the United States, as a greater supply is available there than in other countries.

The silver and white metal fine chains and wire are a speciality of French manufacturers. The comparatively small quantity of muriatic acid used for polishing purposes is also obtained from France. The coarse files used are obtained second-hand in Europe and can be used and re-sharpened many times in Bethlehem. The total amount purchased in a year is insignificant.

TOWN PLANNING.

The third annual report of the Ministry of Health says that it is becoming increasingly recognised that the policy of town planning is not only one which will guard the future growth of towns against the inconveniences and the serious evils which have been the result of the haphazard development of the past, but that it is, directly and indirectly, a measure for true economy. Many local authorities have by now realised how much they will gain by preventing the erection of buildings or other works on routes which will be needed, sooner or later, for important thoroughfares or on sites which will be required for open spaces or other public purposes—industrial, residential or other—for which it is most suited, and, incidentally, securing transport facilities adapted to local requirements, particularly of industry, and they see the importance, generally, of making plans in good time so as to ensure that the operations of the private developer may harmonise with public needs, thereby often saving the necessity for public expenditure without any hardship to the owner, and also of taking precautions so that when public works have to be executed they may be carried out at a minimum cost.

The total number of local authorities which had proposed or were engaged in preparing town planning schemes on the 31st March, 1922, was 167, the whole area covered by these schemes amounting to 744,222 acres. Considerable progress has been made with the preparation of model clauses for town planning schemes, and it is hoped that it will be possible to issue them very shortly. During the year under report twenty Interim Development Orders were issued under Section 45 of the Act of 1919. Further Joint Town Planning Committees have been formed during the year and others are under consideration. These committees are advisory, their functions being to prepare an outline plan and statement of development for the entire region concerned and to advise on the co-ordination of the schemes of the various authorities as they progress.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

THE MECHANICAL DESIGN OF SCIENTIFIC INSTRUMENTS.

By PROFESSOR ALAN F. C. POLLARD,
A.M.I.E.E., F.Inst.P.

LECTURE III. *Delivered March 6th, 1922.*

In the course of the lectures, reference has been made to the variance of measuring instruments, and we have examined various designs, one object of which is to reduce variance to a minimum. We will now examine in detail the different mechanical causes of instrumental variance. Before we do so, however, it will be as well to have a clear idea of the relation of variance to accuracy, and sensitivity, and we shall follow the extremely important notions of J. Schlink*.

It sometimes happens that the distinction between accuracy and sensitivity is not always maintained in the discussion of physical and engineering scientific instruments. The fundamental concepts are of course, quite clear.

An instrument is said to be:—

- (i.) Accurate when its indications accord with the true value of the quantity being measured.
- (ii.) Sensitive when a change in the quantity being measured is accompanied by a change in the indication of the instrument.

We know that we can never have perfect accord between the indications of an instrument and the values of the quantity being measured, so the definition is an ideal which is never attained. The various unavoidable mechanical limitations imposed by the coaction of the working parts, friction, alterations in the dimensions and

properties of the instrument's elements with time, and the changes in the environment, of temperature, pressure, humidity, etc., and normally uncontrollable variations in the manner, frequency and rate of operation, all tend to make the accuracy of the instrument depart from the ideal. We require some quantity which will show us by how much the instrument departs from this ideal, and at a given reading the actual value of the discrepancy is termed a "correction."

In the common measurements of industry and commerce, sufficient accuracy is sought in the instrument so as to dispense with corrections, in order that the readings of the instrument can be used directly without a correction in a convenient manner.

But in laboratory instruments, or where greater accuracy is required, the instrument is calibrated against some standard and the corrections or errors are discovered at points closely set along the instrument's range.

Instrumental accuracy is usually expressed numerically, by defining the error or correction for various values of the quantity being measured. The error arising from whatever source, observed in an indication of the instrument, divided by the true value of the measured quantity may be termed the relative or *specific inaccuracy* at a given reading, the negative term being justifiable on the basis of custom and ease in application.

The reciprocal of *specific inaccuracy* may be termed *specific accuracy*, a ratio which is not of value in the ordinary use of instruments, but of service in rating the performance of an instrument.

By the commonly accepted definition already given, any instrument which shows a change of reading for any change, however great in the quantity being measured, is sensitive.

For particular instruments, especially those read by null methods, sensitivity has

*Bureau of Standards. Vol. 14, p. 741.

often been expressed as the smallest change in value of the measured quantity which produces a perceptible response in the indicator of the instrument. Expressed in this way the term sensitivity is unscientific and loose, since differences in the observer's acuteness of perception or personal sensitivity would result in varying estimates of the sensitivity of the instrument.

Moreover, using the term in this way we should fail to distinguish between insensitiveness and sluggishness or want of response.

For example, the sensitivity of a balance was long defined as the smallest added load which effects a perceptible change in the position of the pointer.

Analytic balance makers even now express the sensitivity as "turning to so many milligrams." Obviously, the beam might be sluggish and it might turn to a smaller load than that stated if left to itself long enough. The definition has since been improved by measuring the distance the end of the pointer moves through for change of unit load on one of the scale pans. But this is not sufficient, for the sensitivity of any one balance could be increased by making the pointer longer.

A scientific way of measuring the sensitivity of a balance is to state the angular displacement of the rest position of the beam when unit load is added to or taken away from one of the pans.

In actual measurements of sensitivity of instruments the deflections of the indicator must be small, principally because the sensitivity may vary over the range of the scale. The deflection used in determining sensitivity must, therefore, be so small that variations over that range of deflection are quite negligible.

Sensitivity then is the rate of displacement of the indicating element with respect to change of the measured quantity, *i.e.*, $\delta\theta/\delta m$. But it may happen that on account of friction between the moving parts of an instrument some definite change δm in the measured quantity fails to produce any change $\delta\theta$ in the indication.

If, therefore, we plot as a Cartesian diagram, the indication of the instrument against the measured quantity, as shown in Fig. 33, we should have a zero sensitivity at some point in this "measured quantity—indication curve," which in reality has a definite slope or sensitivity at that point.

On this account it becomes necessary to

FIG. 33

draw a distinction between sensitivity and want of response.

In fact, it is often true that in less precise instruments a considerable change in the measured quantity can be effected without any motion in the indication of the instrument. This period of inaction of the indicator persists during the taking up of slack and the overcoming of the static friction of the operating parts.

We thus distinguish between instrumental "passiveness" or sluggishness and instrumental insensitiveness which was first pointed out by Schlink.

Passiveness may then be determined by noting the smallest alteration in the quantity to be measured which will produce any change whatever in the indication of the instrument.

The specific term is:—

least change δm in the measured quantity producing instrumental response.

Passivity = $\frac{\text{Initial value } m \text{ of the measured quantity}}{\text{least change } \delta m \text{ in the measured quantity producing instrumental response}}$

In the diagram the curve at the initial value m becomes horizontal over a range δm and I have indicated the finish of this range by a small damped oscillation of the indicator in order to bring clearly before the mind the inactivity of the indicator, which being overcome by the growing forces acting upon it as the measured quantity increases oscillates about its position of equilibrium assumed to be on the curve.

We rejected the notion of a perceptible movement so far as it relates to sensitivity, but we may retain it for the definition of passiveness, since the passiveness evidenced by delayed response has been overcome so

soon as any motion whatever of the indicating element has taken place.

The notions with which we have just dealt are related to the measured quantity.

We now deal with a set of notions regarding the performance of the instrument which exclude the variation of the measured quantity and in which all changes of indication are intrinsic to the instrument itself and are not, *per se*, indicative of change in the measured quantity. The term, variance, conveniently covers these changes and it may be defined as the range, at any given value of the measured quantity, of variation in reading which may be exhibited by the instrument under repeated application of the same value of the quantity being measured, after a steady reading has been attained, the environment remaining unchanged. The specific variance or *variancy* is the ratio of this range divided by the value of the measured quantity itself.

Variance which overlaps passiveness is in reality the range of uncertainty of indication, when all the causes of variation save those inherent in the instrument are eliminated. This factor is rarely determined in tests on measuring instruments. Its neglect may cause appreciable error in conclusions inferred from the indications of the instrument, and its investigation will certainly expose instrumental imperfections of considerable and hitherto unsuspected importance.

In the case of the usual direct reading instrument, the variance is disclosed as the displacement observed between the upward and downward branches of a hysteresis loop when the instrument is subjected to a complete cycle of operation from a lower to a higher indication, returning again to the lower indication.

This curve, showing the errors in the readings of the instrument over its whole scale range, is a valuable, and, in fact, indispensable, index to the operating characteristics of an instrument, and affords information regarding defects of design and workmanship discoverable with certainty in no other way.

Fig. 34 shows the hysteresis loop of an automatic or self-indicating weighing scale of the cam-pendulum type, in which the load is balanced by the variable turning moment of a pair of oppositely rotating pendulums mounted on ball bearings, and which, therefore, comprises no elastic force elements. It will be seen how the aber-

(After Schlink.)

FIG. 34.

rations of the increasing readings are reflected in the curve of decreasing readings with a tendency to wider separation at the middle of the load range. The hysteresis is certainly not due to elastic strain, though, no doubt, the elastic strain of the coating elements contributes a small and negligible amount, as in all instruments.

The sources of this hysteresis loop are all expressible as back lash, or are closely analogous to it. The next figure gives the

(After Schlink.)

FIG. 35.

hysteresis loop of a depth gauge for gasoline tanks, which is a diaphragm type of pressure gauge. The ordinates are in inches of gasoline and here, obviously, the variance is due to want of elasticity of the diaphragm. This type of variance is present in all instruments which use a spring element in equilibrating the changes in the measured quantity. The changes of shape of spring elements are always to some extent irreversible. The errors which the flexure of astronomical transit telescopes introduces into the readings of these instruments are

exceedingly troublesome and difficult to determine.

It would be interesting as well as extremely important to astronomical observation, if the hysteresis loop of transit instruments could be determined for the range of the instrument over the meridian. It might then be possible to analyse the loop into its types of variance and improve the design.

We cannot ever eliminate flexure from the parts of our instruments, but we can, by the choice of suitable material, and by design, reduce it to the necessary minimum. When a bar of material bends under load, the fibres of the material are stretched or squeezed, and we know that, if we do not exceed the elastic limit, the stretching or squeezing of the fibres is proportional to the load.

The intensity of the load is then, equal to the stretch or squeeze multiplied by a constant. This constant is the modulus of longitudinal elasticity or Young's modulus. Hence, if we choose a material with a large Young's modulus, the stretch or squeeze is less for a given intensity of load.

No one would dream of making the limb of a microscope of oak in preference to steel, and one of the reasons is that Young's modulus for steel may be 35 times as great as Young's modulus for oak. Generally speaking, instruments are mechanisms, but are not machines; that is to say, they are not mechanisms whose chief function is the transmission or commutation of energy. Their chief function is to maintain determinate geometrical relations between the links of the mechanism.

It is only necessary then to investigate the elastic aberrations of the geometrical relations, and to ensure that these elastic aberrations do not cause error at the indicator exceeding some determined fraction of a unit division of the scale.

Frequently the design of analytic balance beams shows great ignorance of the theory of framework. The correct shape of a balance beam is two equilateral triangles placed back to back, in order to secure maximum stiffness with minimum weight. The cross sectional dimension of the links of the framework should be settled by the permissible deviation of the knife edges from their original relative positions in the vertical plane when the pans carry the maximum load.

This permissible deviation is settled by the required sensitivity at the maximum load.

By using graphical methods (on the drawing board) of solving elastic problems, a straight prismatic piece of any cross sectional shape though defying pure analysis can easily be investigated and the correct form determined for a definite deflection under a given load. It is more troublesome to deal with a curved piece in which the radius of curvature is comparable to the dimensions of the cross section—it requires excessively accurate draughtsmanship.

The supporting parts of the framework, however, may be subjected to external forces during manipulation of the instrument which cannot be specified.

In these cases the model is the only source of information.

Another type of variance is due to friction, and we have already indicated this under the term passiveness.

The main type of variance is that due to back lash, and analogous mechanical imperfections.

In instruments the chief function of turning pairs is to maintain constancy between the parts of the mechanism which transfer the forces or motions involved from the point of their reception to the point of registration or indication. This implies kinematically a constancy of virtual length in the linkwork if comprising only lower pairs or a constancy of determinate virtual length for any given configuration of the link work if comprising higher pairs. Let us examine the case of a single bearing having a loose journal thus representing the allowance for a running fit.

1 and 2 are two links of the mechanism of a measuring instrument. To fix the ideas the instrument may be a hair hygrometer shown in Fig. 36.

During operation the links 1 and 2 rotate about some more or less definite centre.

Assuming that force closure exists to keep the bearing and journal in contact at some point *m* and the hair 3 taut, the journal in part slides and in part rolls around the interior of the bearing, and its centre describes the arc of a small circle whose radius is equal to the difference of the radii of the journal and the bearing.

The point (1, 2) then for ordinary motions of the instrument will have motion in this arc, and it is at once evident that the movement of the pointer tip over the scale *A* does not bear a simple geometric relation to the change of length of the link 3.

(After Schlink.)
FIG 36.

In the case of a spindle rotating in ball bearings the exact performance may be different from the case I have just described, but the effect will be the same.

When the maximum sideways displacement of the instantaneous centre of rotation is reached, a more or less steady state of slipping takes place, so that as far as the hysteresis loop is concerned it is expected to be flat in this portion of the operating range.

The loop will then be made up of three phases—a lower lenticular portion, a middle oblong part and an upper lenticular portion. This state of affairs can be demonstrated by experiment.

Clearance between teeth of engaging gears and racks introduces backlash effects of the same general nature as those outlined above.

In many cases the backlash of gear elements will be superposed upon that of turning pair elements.

In well made instruments the variance we have indicated will reproduce itself with considerable constancy, but in instruments which are badly made or in a state of ill repair, the hysteresis loops obtained in successive runs may be far from concordant in either shape or magnitude.

This irregular variance may be well expressed and defined by reference to a family of probability curves developed at various points along the instrumental scale.

Such readings in the calibration require, therefore, treatment similar to that required

for "the errors of observation" by reference to the theory of probability.

Another type of variance is that due to drift and we have already referred to this in the case of aneroid altimeters. Drift is a time effect characterised by the gradual movement of the indicator asymptotically to a definite reading.

The cause of drift does not originate in the kinematic relations of the linkwork, but is due to an elastic after-effect present in almost all diaphragm instruments or a viscous resistance in the case of indicators, for example, moving in viscous liquids such as hydrometers, or the slow movement of heat through the protecting sheath of pyrometers, or temperature changes due to flow of current in certain electrical instruments.

The elastic after-effect is indicative of over-strain such as most certainly exists in the corrugated diaphragms of aneroids, for example.

From what has been said, it is evident that variance or the reproducibility of reading will limit the useful sensitivity, and the graduation of instruments is often found to be far closer than the large amount of variance justifies.

For testing or laboratory instruments, the mean interval of graduation should not be less than five times the mean variance, since observations may be noted accurately to 1/5th the smallest graduation.

For commercial instruments the unit of graduation may be to the variance in the ratio of 2 to 1.

It is obviously absurd to graduate a tachometer to one revolution per minute, when the variance may be as much as five revolutions per minute. Yet instruments are frequently graduated in this way. I have myself seen chemists laboriously reading burettes to 1/50th of a cubic cm., when the amount of liquid which clings to the walls of the tube will amount to several tenths of a cubic centimetre after the contained liquid has descended from a high to a low level.

Nearly all instrumental indications are references to a length which is proportional to the quantity being measured. Angular indications are referred to length of arc, areas by planimeter to length marked on the circumference of a drum, volumes by stereometer to length of liquid column, etc. Even in the analytic balance, weight is ultimately referred to the distance of the

rider along the beam, or the distance the pointer is displaced from zero position.

It sometimes happens that the length to be measured has directly applied to it a measuring rod in some form or other.

Such, for example, is the case when determining the height of the barometer. The level of the mercury in the tank is brought to some fixed level by observing the reflection of a fixed point in the surface, then the upper level of the column is determined by the coincidence of a fiducial edge with the meniscus, as seen through the irregularly refracting glass wall of the tube.

The late Lord Rayleigh* pointed out several years ago, that such a method of applying the two ends of the measuring rod in different ways is unsatisfactory, and in his accurate work upon gases he used measuring rods of iron for the manometers by means of which the differences of the mercury column heights were determined by the same physical procedure.

A vertical rod had its lower end pointed, and its upper end made into the form of an inverted stirrup from the centre of the horizontal limb of which a second point was directed downwards. The length between the two points could be accurately measured, and the coincidence of them with their reflected images in the two mercury surfaces of the manometer, insured a high

have hinted at economy of production. Economical production is, of course, a gigantic field of activity, even when considered in relation to the manufacture of instruments, at which we can but peep.

But in doing so we shall learn that design having reached the last stage now divides itself into two main types—functional design and manufacturing design. In the early days the inventor brought to the mechanic his ideas and design was an outcrop of the mechanic's mind. He altered this or that part until the mechanism behaved in a way which pleased the inventor. The model was corrected and rebuilt before the design was completed. Duplicate mechanisms were copies of this model, possibly modified again by the mechanic's improvements or by the supply of material.

Interchangeability did not exist in these early days except in a prominent instance. The demand for wheels and pinions for clocks and watches became so great that the famous Dr. Hooke suggested a machine for dividing and cutting the teeth in wheels and pinions for clocks and watches in the latter part of the 17th century. The first machine, according to Hooke's notions, is said to have been made in France and to be similar to the machine figured and described in Bion's work on mathematical instruments, 1702.

FIG. 37.

degree of equality between the height of the mercury column and the known length.

We have now lightly touched upon a few aspects of the mechanical design of instruments in so far as their functional requirements are concerned, and in doing so, we

Fig. 37, taken from a later edition (1758 of Bion's work, shows this little machine in plan and side elevation, as well as some of its parts separately.

The plate A of brass, about 8" in diameter, has a series of equally spaced holes drilled in it on various concentric circles, similar

to the dividing plate of some modern lathes.

The plate fixed to the arbor shown at Fig. 5 can rotate in the frame 3 and 5, Figs. 1 and 3. Along the bar 3 of the frame a carriage, Fig. 2, can slide and be clamped in any position. This carriage carries the milling cutter with its pulley 1 pivoted between two steel points secured by screws 7, 7 in the piece called the *Porte-Touret*, which in turn is pivoted at 2.

The thickness of the cutter is equal to a tooth space.

The disc to be cut is clamped to the arbor and the carriage is clamped to the bar in such a position that when the cutter is rotated by a bow, the string of which is looped round the pulley, and lowered upon the disc it cuts a tooth to the correct depth.

The spacing of teeth is done by rotating the plate and securing it in position by a fine steel point, Fig. 4, also clamped to the bar 3, engaging with an appropriate hole in the plate—in much the same way as division is done on some modern lathes.

This machine is probably the first which manufactured interchangeable parts.

The French were ahead of other nations in the invention of tools and apparatus for making clocks and watches.

In a work entitled *Traité de l'Horlogerie Mécanique et Pratique* par Thiout, Paris, 1741, there are detailed engravings of three gear cutting engines, two with perforated dial plates and one with a worm for spacing.

The manner in which the dial plates were divided is not clear, but about the same period Henry Hindley (a clock and watch maker of York) constructed a machine for cutting gears with a divided dial plate. In a letter to John Smeaton, of the 14th November, 1748, he describes how he divided the plate by a mechanical device, which we should call a "jig." So he may be regarded as the first inventor of the "jig."

Sketches and drawings next came into use to supplement the inventor's ideas, but all essential constructive detail was left to a competent mechanic and it was part of his training to supply the missing detail. More complete drawings which gave all the necessary dimensions and perhaps more closely specified some of the most important functional surfaces of component parts came later, and such drawings which specify the functional design, which aid the general construction of the mechanism and give general outlines of detail parts are largely used to-day.

But under the manufacturing conditions of to-day, with productive operations divided into elementary parts, with productive labour trained in specialised directions, with highly specialised productive equipment, with the economic necessity of interchangeability of parts, with the greatly increased rate of production and with large organisations, in which but a few individuals are conversant with all the detailed requirements of the mechanism and no one individual is capable of dealing with the mass of detail necessary for a complete and successful issue, the design must cover a wider field, it must be more comprehensive and accurate. Such design is manufacturing design, which cannot even be approached except by those who have had a comprehensive and intensive training as actual workmen in the shops.

Manufacturing design is a later and detailed development of functional design, and is in no way antagonistic to it, as some think. It, in reality, gives the information originally supplied by the mechanic in the early days.

It corrects and modifies the functional design to ensure economical and increased production.

It must ensure the ready assembly of the parts, so that the assembly costs are reduced to a minimum.

It must ensure that parts requiring attention in service are accessible, so that the service costs are reduced to a minimum. This latter requisite can only be completely determined after the instrument has been in service, for it is invariably subjected to abuses which the constructor never dreams of, but for which he is blamed.

Manufacturing design is never complete—improved methods of manufacture are constantly being developed.

It is true that manufacturing design will, in the course of time, work itself out in practice, but this is a slow and expensive experiment on a large and highly uneconomic basis. Continual alterations in equipment spell loss of interchangeability.

The experiment can be carried out on a smaller scale with better, speedier results, with more economy, and the use of models is from this point of view self evident.

These considerations do not interest the manufacturer of small quantities, but, nevertheless, to him as well as to the large producer, simplicity of design is the key to economy of production.

In addition to simplicity of design, there are a host of considerations the designer must keep constantly in view in order to fulfil all the demands of economic production. I refer now to that important, one might almost say branch, of design which requires a complete knowledge of not only how the various mechanical operations are carried out in shops and by machine tools in general, but more particularly in that individual factory which is constructing the instrument.

This essential knowledge can only be gained by an apprenticeship and close study during this important period of training, which is frequently regarded as a nuisance by manufacturers.

How a knowledge of manufacturing processes modify design has been set forth in a series of illustrated articles* which appeared in *Machinery* and which are worthy of careful perusal.

It is quite impossible for us to examine in detail examples of various defects in design from this point of view, but it will be advantageous to set out some of the practical points to be observed in the form of a list of precautions.

In the design of parts which will appear as castings, care should be taken to avoid :—

(a) Insufficient clearances between the surfaces of the casting, and other parts which may be assembled in proximity. It frequently happens that casting irregularities such as lumps due to the falling away of the sand in the mould, may foul another part during assembly, and interfere with continuous and rapid production.

(b) Coreing on small castings, which frequently necessitates unnecessary machining.

(c) Large cores with small outlets.

(d) Loose pieces on patterns which frequently get lost and sometimes displaced when ramming the sand in the mould, with the result of faulty castings.

(e) Insufficient metal on internal bosses which, being liable to displacement, may not stand up to machining.

(f) Complicated shapes. Design rather several pieces each of simple shape to be assembled subsequently.

In parts to be machined avoid :—

(a) Faces in enclosed positions. Neglect of this frequently requires the construction of special tools and nearly always embarrasses the machinist, resulting in bad finish.

(b) Blind holes, which frequently result in faulty work, due to the wandering of drills if special drilling jigs are not constructed and used.

(c) Internal slotting which is an expensive operation compared with shaping or planing.

(d) Insufficient landing space for planing tools in recesses or confined spaces. Room must be left for the tool to come to rest on reversal to the cutting stroke.

(e) Lugs, bosses or other extensions on faces to be machined.

(f) Several faces on different levels, necessitating a resetting of the tool for each face.

The stresses which are set up in castings by differential rates of cooling of the parts while the metal is in the mould or after the mould has been knocked away sometimes reach magnitudes that render the castings unsuitable for use, and in cases of some cast iron castings which have come under my observation have caused violent fracture to develop.

It is important that the cast parts of instruments should be free from these "initial stresses," which are subject to secular variation and to this end care must be taken that large masses of metal which have a low rate of cooling are not connected to small masses which have a high rate of cooling. The smaller mass having cooled acts as a rigid constraint to that portion of the casting connected to the larger mass which is still contracting.

Some interesting and very instructive experiments were carried out a number of years ago by Lieut.-Col. H. Clerk* on the curious behaviour of rings, hoops and other shapes of metal repeatedly heated and partially cooled in water, and the results were remarked upon by Stokes. These experiments seem to have been forgotten, but they should certainly be studied by the student of casting strains, and are of some importance in practical application, such as the tiring of wheels.

The instrument must be produced by established plant with the existing manufacturing equipment or new plant must be created. In both cases unless the volume of production is very large, all efforts must be made to reduce the machined surfaces of the components.

An excellent example of this has been kindly supplied to me by Mr. Stafford, of Messrs. Taylor, Taylor and Hobson, of

**Machinery*. Vol. 14, p. 397; vol. 13, p. 705; vol. 16, pp. 527, 546.

**Roy. Soc. Proc.* Vol. xli., 1863, p. 453.

Leicester, and is exhibited in the clinometer Mk. III., the War Office design of which is shown in Fig. 38 and the redesigned instrument for mass production is shown in Fig. 39.

FIG. 38.

FIG. 39.

In the former the casting was machined all over, involving unnecessary work and expense and imposing an unnecessary limit to the output. The cost of this instrument was about £4 each and the maximum output about 40 per week.

In the redesigned instrument all parts were made interchangeable, the machined surfaces were reduced to a minimum and unnecessary operations were eliminated; thus reducing the cost to about half that of the War Office design. The maximum output was 250 per week, using approximately the same number of operatives, but employing accurately made tools and gauges to ensure rapid, interchangeable and accurate work. All unmachined parts of the casting are enamelled. Some of the details of the instruments are worthy of comparison.

The arm in the new design shows a

much simpler form to manufacture than that in the War Office design. In the latter, the bar is machined with shoulders at either end, which serve the purpose of stops for the slider. This necessitates not only an exact length between the shoulders, but an exact length for the slider itself, an unnecessary complication avoided in the new design. The slider and bubble in the War Office pattern has a number of loose parts screwed together, requiring exact fitting, and the plunger side plates give little finger hold. In the re-designed instrument, the plunger side plates were made from drawn section pressed into shape, thus eliminating a good deal of the machining visible on the War Office model.

Another excellent example of a well designed mass production instrument is the refractometer, patented by Mr. William Taylor*, of Taylor, Taylor & Hobson, and manufactured by Bellingham & Stanley. The internal mechanism of this instrument has, in part, been described and shown in Fig. 20.

The manufacturing design must contain the specification of material.

As many parts as possible should be made of the same size and kind of material, which should be of standard sizes and forms purchasable in the open market at lowest prices. Frequently special and expensive material can be machined at a lower cost with resulting economy in product. For this reason special extruded bars are used in the manufacture of calculating, counting and type-writing machines, which, according to our definition, are instruments.

The source of supply of material must be considered—lack of material spells disaster to production.

Interchangeable manufacture itself involves the establishment of suitable limits on the functional surfaces, and means of enforcing those limits. By limits, I mean tolerances and allowances conjointly.

The limits are the laws of production, and the more liberal they are, the more economic is manufacture.

The importance of the correctly dimensioned drawing in this respect, apart from the specification, is emphasized by the frequent neglect of this important link in manufacturing design. There are two classes of drawings:—

*Patent Specification, No. 178, 290.

(a) Functional drawings ;

(b) Manufacturing or component drawings.

The functional drawings, like the functional design, specify the functional conditions to be maintained and the details which do not appear are supplied by the mechanic who uses them. They do not, for example, specify limits.

Manufacturing drawings, however, must supply all the information necessary for economic production.

One of the chief duties of the manufacturing drawing is to give the necessary tolerances and allowances of the components, so that they may be interchangeable, and in such a way that there is only one interpretation. It would be quite impossible, in the time at my disposal, fully to discuss

the five rules of dimensioning which have been so ably laid down by Buckingham, engineer to the Pratt and Whitney Co.

We may, however, illustrate his first two rules by an exceedingly simple case, involving elementary and not composite surfaces.

Buckingham's first rule is :—

There is only one dimension (or group of dimensions) in the same straight line which can be controlled within fixed tolerances.

His second rule is :—

Dimensions must be given between those points which it is essential to hold in a specific relation to each other.

Fig. 40 (i) shows a stud dimensioned in the usual but incorrect way, for it violates the two rules given above.

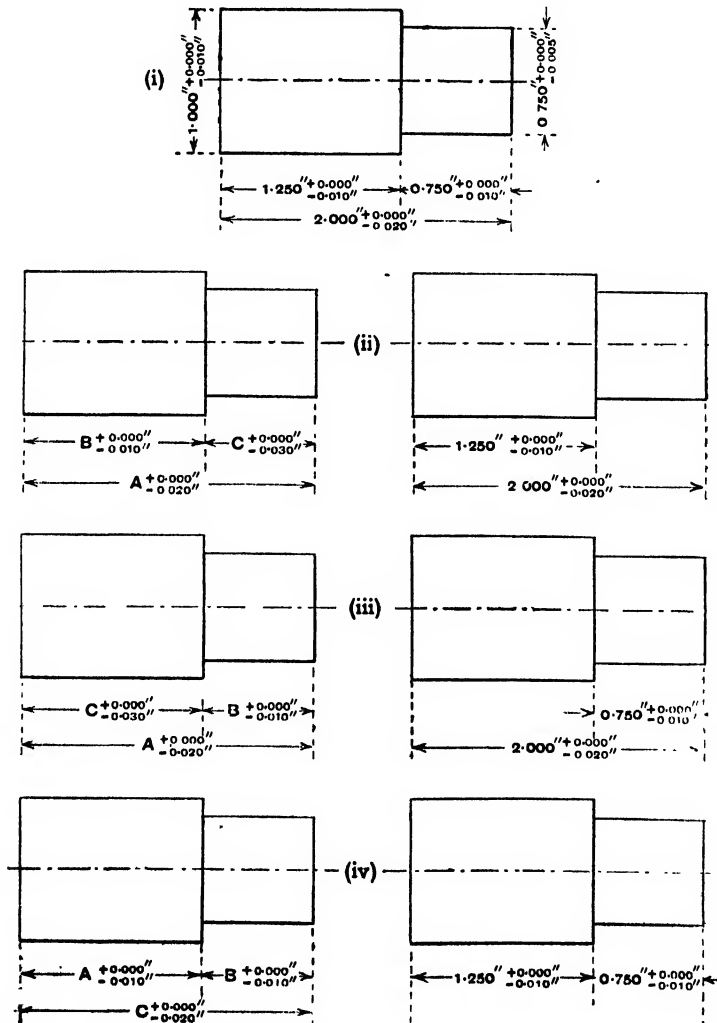

FIG. 40.

As the dimensions for the diameters are correctly given, we can eliminate these from the discussion and confine our attention to the wrongly given dimensions for the lengths.

Fig. 40 (ii) shows a possible sequence of operations indicated alphabetically. If we establish the overall length A and then the body length B, the stem length C may vary, .030" instead of .010" as specified.

Fig. 40 (iii) gives another sequence. If we first establish the overall length A and

liable to develop compound limits and the ambiguity must in all cases be avoided by suitable dimensioning.

The enforcement of limits is achieved chiefly by means of physical gauges.

These are well known to you, but I cannot refrain from describing the beautiful design of a limit gauge by Mr. William Taylor.

This gauge, originally intended for checking the diameter of the screws of photographic objectives and their flanges, is a geometrical design.

Fig. 41.

then finish the stem B the body length C may vary .030" instead of .010" as specified.

Fig. 40 (iv.) shows a third sequence, which is evidently the one intended, because the case happens to be the simplest possible. If we first finish the body length A and then the stem length B, the overall length C will be within the specified limits, and this last dimension is superfluous.

There are, therefore, three possible interpretations of the drawing, Fig. 40 (i), and these interpretations are correctly shown on the right hand side of the three lower figures.

If three different plants were manufacturing this part to drawing (i), it is evident that three different products might be received from them and interchangeability would be impossible.

The violation of these two rules alone could lead to utter confusion in components of complicated form.

I would like to have brought before you striking cases in which a violation of Buckingham's rules result in the imposition of closer manufacturing limits than are actually necessary for the functional requirements of a component and the importance of this cannot be overestimated for interchangeable economic production.

Confusion will also result from the introduction of compound limits. A compound limit exists when the application of a limit to one dimension develops a variation in another dimension, which also has a specified limit. Composite surfaces are

As seen in Fig. 41 the gauge consists of two steel sockets clamped on a truly cylindrical rod, each socket holding two hardened and accurately formed steel cylinders of specified diameter.

Fig. 42.

Each steel socket, Fig. 42, has one large and two small 45° V's cut in it, all three grooves being accurately at right angles to one another.

A ring with a threaded stem loosely fits the cylindrical rod and by a nut maintains moderate pressure between the rod and the two faces of the larger V groove in the socket. Thus the two sockets can be quickly and accurately clamped in any relative position on the rod.

By suitable clamps the small steel cylinders are held up against the small grooves, which are cut so that the axes of the two cylinders in each socket will lie accurately in planes perpendicular to the axis of the rod.

Three of these little cylinders have the same diameter. The fourth has a diameter exceeding the others by an amount which is equal to twice the required limit.

Suppose, now, the gauge is placed in its

FIG. 43.

setting jig, as seen in Fig. 43, and the sockets clamped on the rod in such a position that a standard end gauge fits between the curved surfaces of two of the cylinders, with equal diameters. Then the inside distance between the other two cylinders will be less than the standard by the specified limit. In the same way, the measurement outside one pair of cylinders is greater than that outside the other pair, by the specified limit.

The gauge is a perfect adjustable working calliper gauge, which can be set to any reference end gauge, and the working surface of which can always be checked by micrometering the diameters of the gauge cylinders. These, if found to have developed flats, can be renewed by simply turning the little cylinders in their grooves.

Further, any limits for the gauge can be at once supplied from a set of fourth cylinders and the form of the whole device is peculiarly well adapted to delicate manipulation on a work.

The physical gauges of late years—especially during the Great War—have, in many applications, given place to optical gauges in which the principle of the interference of light is used, and others in which the shadow of the contour of the component is compared with that of a standard diagram, or that of a standard component.

An exceedingly beautiful optical gauge of the latter class is that of Wilson, for checking screw spindles in particular, or any spindle in general, which is constructed by Messrs. Adam Hilger, Ltd.

In conclusion, I desire to express my indebtedness to those who have made these lectures possible by generously lending valuable models and instruments.

I thank Mr. R. S. Whipple, of Messrs. The Cambridge and Paul Instrument Co., to whom time and trouble are of no account when helping others; Mr. Twyman, of Messrs. Adam Hilger, Ltd.; Mr. Ronald Taylor and Mr. Stafford, of Messrs. Taylor, Taylor and Hobson, Leicester; Mr. Swift, of Messrs. James Swift & Son; and Messrs.

Bellingham & Stanley, for the loan of the beautiful instruments which have been shown.

My acknowledgments and thanks are also due to Mr. R. S. Whipple, and the Council of the Optical Society, for permission to use Figs. 13, 17, 18 and 19, and to the several sources from which many of the illustrations have been taken.

[At the conclusion of the lecture, the Wilson Projection Comparator was demonstrated by Messrs. Adam Hilger, and the lecturer showed the evolution of his totally submerged hydrometer, which is an instrument with five degrees of freedom, from the first conception and the first models.]

THE ESTHONIAN TIMBER TRADE.

The Russian Correspondent of the *Timber News* contributes some interesting particulars of the timber trade in Esthonia.

Ever since the end of the war the timber market of Esthonia has continued rather dull. The Esthonian Government had then just taken over the control of the State forests (managed before by the Russian Government) as also of the forests once belonging to private owners. The prices for hewn and sawn timber, which were fixed at that time by the Government Timber Department, were far too high to encourage the trade, and the export of Esthonian timber came, therefore, to almost a standstill.

When finally, in 1921, the prices were lowered by the Timber Department, the foreign markets experienced such a serious slump in business that the export trade was again unable to develop. This year, however, when the foreign markets seem to have reached a stable level, Esthonia is once more re-entering the British market with supplies of sawn soft-woods, sleepers and pitprops.

Esthonia's present production amounts to roughly 350,000 cubic fathoms per annum, of which nearly 300,000 cubic fathoms are absorbed by the home market, leaving about 50,000 cubic fathoms for export abroad. Most of the timber exported is consigned to the United Kingdom and consists of fir, those small quantities of birch which are out being almost entirely consumed by Esthonia's own requirements.

The exports for the first three months of 1922 amounted to £40,000 against £20,000 in 1921. These figures will naturally experience a considerable augmentation during the summer months, when they may easily reach double their above-stated value.

Next in importance to the Estonian softwood trade stand exports of plywood, articles manufactured therefrom, and furniture. The value of the export of all these goods in the course of the first three months of 1922 exceeded that of the softwood by £15,000, amounting to no less than £55,000. Considerable quantities of these goods were shipped to the United Kingdom, but Scandinavia, Germany and the surrounding countries also absorbed a fair proportion of them.

Estonia's position would have become far more important than it is now had the stipulations of the Russo-Estonian peace treaty matured, according to which Estonia should have enjoyed the control over a considerable area of Russian forests. Like most of the Russian promises, this hopeful stipulation never became effective, and instead we notice the Russian Government dispatching their logs to the Estonian mills (principally around Narva) to be sawn there for export. It should, therefore, be clearly understood that timber shipped from Estonian ports need not always be of an Estonian provenance.

There is no doubt that the Estonian timber trade may look forward to great developments once the Russian concession becomes operative, but until then nothing exciting can be expected from those quarters, except that a limited supply of really good quality softwoods will be available this season and that considerable quantities of manufactured timber, as plywood, etc., will be produced in ever-improving quality.

VEGETABLE OIL AS MOTOR FUEL IN BELGIAN CONGO.

The extremely high cost of transportation of motor spirit into the interior of the Belgian Congo, largely due to tsetse flies, which make it impracticable to use animals for transporting goods and necessitate the use of native porters, led the Belgian Colonial Ministry to organize a trial of road tractors using palm oil as fuel. The results of these trials, according to the official United States "Commerce Reports," have opened up vast prospects for the development of Central Africa, and may be summarized as follows:—

Palm oil, when used as sole fuel in semi-Diesel two or four cycle engines, gave full satisfaction. The engines ran normally, and the power developed is equal to, if not greater than, that obtained with kerosene. Nothing was noted that suggested possible difficulties in using palm oil in these engines. Starting up, without motor spirit injection, is good, and

there is no carbonization. One large firm, which holds diamond and rubber concessions, possesses three tractors that run on palm oil and have ordered two more, very satisfactory service being rendered by those which have been in operation. These tests would indicate, then, that vegetable oils, which are so abundant and cheap in the tropics, can replace other fuels for semi-Diesel engines which are suitable for tractors, as well as other vehicles and machinery.

PERSIAN RUG EXPORTS.

In the 12 months ended March 20th, 1921, Persia exported rugs weighing in the aggregate 698,150 batmans and valued at 50,035,660 krans (1 batman equals 6.5 pounds approximately; the average exchange rate of the kran during the period in question was 50 05 to the £1).

The following table gives details of this trade:—

Kinds.	Quantity.	Value.
	Batmans.	Krans.
Wool carpets, without aniline	437,891	33,544,182
Wool carpets, aniline dyed	251,107	16,421,601
Silk carpets, without aniline	16	6,400
Silk carpets, aniline dyed	136	63,477

From a report by the United States Consul at Teheran it appears that the principal regions of manufacture of wool carpets without aniline were Arak, Tabriz, Kerman, and Hamadan, these four places accounting for over half of this kind of carpets exported. Aniline-dyed wool carpets were produced, principally at Arak, Hamadan, Tabriz, Shiraz, and Kerman, these five regions producing three-quarters of this class of carpets exported. Silk carpets without aniline are manufactured entirely at Kashan, while aniline-dyed silk carpets are made in Kashan, Tabriz, and Shiraz. "Arak" or Sultanabad rugs include those varieties which are known as Mohal, Sarouk, and Kenere (each of these in turn being sub-divided into fine, good, ordinary, and inferior qualities), while "Hamadan" rugs comprise those of the Mossoul variety and are generally known by the latter name.

The year's exports of wool carpets went chiefly to the United States, 281,000 batmans; Turkey, 136,000; British Empire, 96,000; Mesopotamia, 80,000; and British India, 64,000 batmans. Silk carpets were shipped for the most part to Turkey, 53 batmans; United States, 43; British India, 26; and France 19 batmans.

BLANKET TRADE OF THE ORINOCO VALLEY.

No single dry-goods article enjoys a larger sale in the Orinoco Valley of Venezuela than blankets, reports the United States Consul in Trinidad. They are used by the llaneros when driving cattle long distances, by those who gather forest products such as balata, tonka beans, and chicle, and by persons engaged in alluvial gold mining, all of whom customarily sleep in hammocks at night with blankets thrown over them for warmth and for protection against the elements. Furthermore, although the climate of the Orinoco Valley is tropical, the nights are cool and windy, and as the ordinary Venezuelan bed has only a mattress, a pillow, and an under-sheet, those who travel about usually carry blankets with them. The kind most preferred is a cheap-quality cotton blanket, with a design of coloured stripes and flowers.

The "cobija forrada," or lined blanket, obtained exclusively from England, is in general use among cattlemen and those who go about the country on horse back. It is made of old wool, or bayeta, in two layers, one red and one blue, fastened together with threads and with an opening in the centre for the head. These blankets cover the rider very loosely like a poncho and thus permit free use of his hands, but they afford adequate protection against both cold and rain, and the Venezuelan rider looks upon them as indispensable. The lined blanket is supplied in large quantities in the Orinoco River Valley, the retail price being from 50s. to 84s. each.

GENERAL NOTES

NEW ZEALAND BUTTER AND CHEESE.—That the New Zealand dairy industry is big enough in its aggregate export output to make itself felt on the British market is increasingly demonstrated as the present great producing season draws in. Up to April 30th, according to *Ice and Cold Storage*, the gradings amounted to nearly 46,000 tons of butter and 60,000 tons of cheese. The Auckland district alone has contributed over 25,000 tons of this butter, notwithstanding a substantial share in cheese production, and the big quantity of dried whole milk manufactured there. The three-skim-milk powder factories of the New Zealand Co-operative Dairy Co. closed down in April for six months owing to the fact that sufficient powder had been made this season to meet the trade requirements for some time ahead. Butter manufacture is proceeding, however, in connection with these establishments. A number of dual-plant factories in various districts reconverted to butter-making in April. It has been estimated that the dual plants influence the country's cheese output to the extent of 25 per cent. when they switch on to butter, or *vice versa*. As to the London market, it

has been extremely gratifying to note the recent approximation of New Zealand butter prices to those of Danish, and to note, in fact, that on at least one occasion the quotation for New Zealand butter topped the Danish price. It is considered that the extra uniformity of the New Zealand article, derived chiefly from our larger factory units, has had an important influence in the price movement referred to.

INDUSTRIAL DEVELOPMENT IN INDIA—The *International Sugar Journal* records substantial progress with the Nira Valley Sugar Co., floated by Lalubhai Samuldas, of Bombay. Located at Baramati, about 100 miles south east of Poona, the factory is in the centre of a district where 30,000 acres of irrigated Pundhia cane are grown annually. As only 400 tons of cane per day can be dealt with, there should be no difficulty in obtaining an ample supply of raw material. The factory, which will be ready to operate in December next, is thoroughly up-to-date in its design. It will have a 14-roller mill and quadruple effect evaporator laid out for separation of steam to both heaters and pans. Sulphitation of juice and syrup will be employed, and the latter will be filtered before being sent to the pans. Plant for double curing of the massecuites has been installed, and one grade of white sugar, or first and second and third grade may be turned out at will. A note issued by the Secretary of the Sugar Bureau at Pusa shows that in India there are at present 18 factories refining raw sugar, gur or rab.

COTTON IN THE BELGIAN CONGO.—According to a report by the United States Commercial Attaché at Brussels, there are at present in the Belgian Congo between 50,000 and 60,000 small native farms raising cotton and producing on the average 600 to 800 kilos of unginned cotton per hectare (kilo=2.2046 pounds; hectare=2.471 acres). The plots sown to cotton are extremely small and run as high as 10 to 20 to the hectare. Reckoning 476 pounds to the bale, the yield of commercial ginned cotton would amount to approximately one bale per hectare. The present production is estimated at 3,700 bales of 476 pounds each.

NEW KAURI GUM PROCESS IN NEW ZEALAND.—According to a report by the United States Consul at Auckland, a new process for cleaning kauri gum, used largely in varnishes, has been devised in New Zealand, and the delivered product from this operation is 98 per cent. pure as against 80 to 85 per cent. in other processes. It is claimed that this new method of treatment, which has been in operation for a few months, will reduce the time of treatment of the gum from the swamp face to shipping package to two hours, and will reduce the cost by about £3 per ton.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C. (2)

NOTICE.

COUNCIL.

On Monday, the 9th inst., the Council elected Sir Aston Webb, K.C.V.O., C.B., P.R.A., a member of the Council and Vice-President of the Society, in place of Viscount Northcliffe, deceased.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

THE CONSTITUENTS OF ESSENTIAL OILS.

By LIONEL GUY RADCLIFFE, M.Sc.Tech., F.I.C.

LECTURE I. — *Delivered March 20th, 1922.*

HISTORICAL INTRODUCTION.

Essential oils may be defined as volatile, more or less oily aromatic substances occurring in various parts of many different plants. Generally these oils are highly complex mixtures of definite chemical compounds and these individual constituents are to form the subject matter of the lectures.

Chemical research, aided by purely physical methods, has isolated and identified the principal odorous constituents of many essential oils, though much remains to be done, especially in regard to the identification of those constituents which only exist in the oils in exceedingly small amounts and yet exert a very pronounced effect on the odours of such oils. It is, therefore, very clear that the essential oil industry or in a more extended sense, the perfume industry, has received the very considerable attention of chemists in the past, but never more so than at the present day; still, until recently this country had seriously neglected the distillation of essential oil yielding plants and the manufacture of

odorous substances and, indeed, the whole industry was on a very limited scale compared with Continental nations. To this aspect a return will be made later.

It may be truthfully said that in considering the history of the development of the perfume industry, it is in a large measure a recognition of the advances which have taken place in the apparatus used through the ages for the process of distillation. It is an accepted fact that knowledge of the art of distillation dates from the remotest antiquity, but it can only be conjectured as to the precise period at which the practice was discovered. There is but little doubt that in the first instance the delight of man in the fragrance of flowers and fruits led to the desire to possess the odours themselves in a tangible form and available at times when it was no longer possible to obtain the flowers themselves; further, there is much reason to believe that the rose was the first perfume flower to be treated by distillation, whereby what Maeterlinck has called "the imprisoned soul of the flower" was obtained as a beautiful smelling oil known to us now as "otto of rose."

The modern conceptions of essential oils and their chemical constituents began about 18th C., and it became clear that most essential oils were composed of two main ingredients, viz., a terpene, which was a compound of the elements carbon and hydrogen only, and that this was mixed with the second ingredient made up of other substances, which we now know to include nearly every class of organic compound.

At this stage brief reference must be made to the importance of the geographical distribution of essential oils. The British Empire can, and does, produce the raw materials which yield a great majority of the essential oils, but until quite recently full advantage has not been taken in this country of our resources and opportunities. Few will dispute that the ideal condition of a given industry is that the raw materials found in a country should be converted into

the finished article in that country, but this principle, though, of course, recognised, has not been fully appreciated so far as the essential oil industry is concerned, and this mighty empire has allowed the foreigner to buy the raw materials in various parts of our Empire and carry them to his own country to work up into intrinsically valuable oils and the like, and then merchant them to us at prices fixed by himself. Still, it must not be forgotten that this country does labour under some insurmountable disadvantages, inasmuch as certain plants will flourish and certain will not flourish in our climate, and this limits our perfume manufacture to some extent; but we must look over our household, as the Empire includes every kind of climate, and it behoves us to see what can be done within the confines of that vast area upon which the sun never sets. It should be better known that our Colonial Governments have been for some years making efforts to cultivate profitable essential oil-bearing plants, and in conjunction with the Imperial Institute valuable results have been obtained and the prospect should be alluringly bright.

Although it is not the object of this course to deal with the manufacture of odorous substances, but rather with the constituents of such substances, it is necessary briefly to outline the methods of extracting the odours of flowers and the oils from plants, and in this connection our neighbour France holds the pride of place so far as floral perfumes are concerned, and this, both on account of the wonderful climate of the South of France, and the skill and devotion of those men who have given their lives to the study of the facilities and opportunities offered to them by their own country.

Just at the moment the perfume industry is having an anxious and vexatious time, the law for the safeguarding of industries, the question of duty-free alcohol and trade depression are each adding their quota of troubles, but there is no doubt that these difficulties will be overcome, and with a proper understanding of the raw materials available within the Empire, British tenacity and the skill of our chemists, will raise up an industry second to that of no other country in the world, but it means research and costly research at that, and there is yet to be established a central research association for the perfume industry, and this should come into being at once and be liberally supported by everyone

connected with the industry and directed in a truly liberal spirit.

In very briefly reviewing the methods used for the extraction of odorous substances from plants, mention may be made of the knowledge, etc., which must be available before the extraction proper can be undertaken. A serious scientific study must be made of the conditions of cultivation required for each odorous plant, this including scientific manuring, etc.; the exact age of a plant at which the maximum yield of the desired essential oil can be obtained, must be chosen as the time for harvesting and the best process, distillation or otherwise, must be used for the extraction of the material, and in addition to this knowledge the raw plant materials frequently require a preliminary treatment, such as rasping, in the case of oil bearing woods, or crushing and grinding for odorous seeds.

The extraction of the odours from delicate flowers is at once a science and an art, and may be illustrated by reference to the floral perfume industry as carried out in the South of France. Probably the most important district in this connection is the Department of Grasse, situated on the Mediterranean sea, and behind it the Alpes Maritimes and the principal town of Grasse itself, situated on the hillside about 1,000 feet above sea level, has an almost perfect climate, so much so that flora of this portion of the Riviera may be said almost to reproduce the botany of Europe. In the Alpes Maritimes, lavender plants (*lavandula vera*) are distilled in quite small, simple and portable stills, arranged in the open air. The plant material is placed in the still with water, and the whole heated over a naked fire so that the steam carries over with it the essential oil, and the mixed vapours are condensed in primitive coolers, which consist of a coiled pipe, immersed in cold water, contained in a kind of barrel.

On a large scale, there are several methods of distillation such as dry steam distillation, with saturated steam under pressure, or with superheated steam, or a simple distillation with water, whilst methods of continuous distillation, and distillation in partial vacuum, are all practised. The stills are exceedingly varied in design, and are often quite elaborate, but time does not permit of a description of these. In connection with distillation methods, it must be kept in mind that in nearly every odorous

material, the exquisite freshness of the original perfume suffers by the process of steam distillation, and the longer the material is in contact with the steam, the greater is the general deterioration of the perfume. At this stage, and in connection with lavender, it must be pointed out that the English grown lavender is quite different from that grown in the South of France, and is accounted a much more beautiful perfume, and in the chemical examination of lavender oils, this difference in the two lavenders must always be kept in mind, and the judgment of the nose added to that of the chemical test.

Returning to the perfume industry, in the South of France the extraction of delicate flowers is carried on by a very different process from that described above. Such flowers as the violet, jasmin, cassie, orange, rose, mignonette, tuberose, etc., are treated by methods which do not alter the most subtle and delicate characters of the perfumes. It will be understood that the cell membranes of flowers are very fragile and easily broken, and that once this happens, the various substances contained in the cells come in contact with one another, and frequently cause changes so that the delicate perfume becomes changed in the flower when once the petals have been bruised. To avoid such damage, the following processes have been devised, and many of them are historically very old. In the first place, there is the method of extraction by fixed, *i.e.*, non-volatile solvents, which, practised with the cold material, is called "enfleurage," and with the hot fixed solvent is designated "maceration." Such delicate flowers as jasmin and tuberose, contain only a portion of the perfume material, which they are capable of yielding, in the free state, so that a method is used which does not kill the flowers, and which permits of the further development of their odorous constituents and the absorption of these, as they are set free by the plant, *i.e.*, the cold or "enfleurage," process. The flowers, after being weighed, are transferred to a table and undergo a process of picking, having for its object the removal of unwanted material, such as leaves and twigs; then the flowers are ready for the treatment proper. The apparatus used is a large wooden frame furnished with a glass bottom so as to produce a tray, which is called a "chassis." The upper surface of the glass

is spread with a layer of fat, and on this the fresh flowers are scattered. At the same time, the bottom of the tray is also coated with the fat, and the trays are made so as to fit one within the other; these are piled in tiers so that each batch of flowers is standing on fat, and has a layer of fat above it to absorb any volatile oil which the flowers may give off, and so the perfume of the flower, gradually disengaged, is absorbed by the fixed fat. Actually, the time required for the flowers to be exhausted of their perfume varies with different flowers; for example, the jasmin flower takes about 24 hours, after which the exhausted blooms are removed and replaced by fresh ones, and the treatment is repeated until the fat has acquired a sufficient strength of perfume. The resulting perfumed fat, known as the "pomade," is the raw material from which the perfumer manufactures his artistic confections. This process is a very lengthy one, and includes the whole period in which the flowers bloom, enormous bulks of flowers are required, and many thousands of trays are in use at a time, in such factories. A "chassis" is about three inches in depth, 24 inches in width, and 36 inches in length, and has placed on it about 1 lb. of fat in all. One of the oldest forms of perfumed fat is perfumed oil. To make this, the glass bottom of the chassis is replaced by wire-netting, on which is placed a piece of wool or coarse cloth saturated with olive oil, and again the flowers are placed on the oiled material and the perfume is absorbed.

The warm process of enfleurage or maceration is applied to such comparatively stable flowers as the violet, rose, orange flowers and cassie flowers. In the process of maceration, large tinned basins, called "bugadières," standing on water baths, contain the melted fat, and in this are placed the flowers, which are kept submerged at a temperature of about 65°C. for about half an hour, when the flowers are removed, drained and taken to a press to remove adherent fatty matter, which is returned to the main bulk. Many treatments with flowers are required, and, roughly, anything from 5 to 25 lbs. of flowers, according to their nature, are required to perfume adequately a pound of fat. In some factories, pure olive oil is used instead of the fat, and is kept heated by a water-bath, and the flowers immersed in it as before, and, in general, the shorter

the time of contact between flowers and warm oil, the more delicate is the resulting perfume. Various devices are in use to reduce the time of maceration; for example, one consists of a reservoir containing the fat heated to about 65°C., from which it flows in a slow stream through the macerating chamber, consisting of a long tank in which wire cages containing the flowers are suspended in open compartments. From time to time, the basket nearest the oil reservoir is emptied and all the other baskets are moved on one compartment, whilst a fresh basket of flowers is added at the other end, this resulting in a constant movement of the oil and the flowers, in opposite directions, whereby the time of maceration is materially reduced.

The extraction of the odorous substance from these fatty materials is a simple, but rather lengthy, operation, and to achieve this object, use is made of the fact that the odorous material is soluble in alcohol, whilst the fat or oil is very sparingly dissolved by the spirit, and thus an alcoholic extract of the floral pomade can be obtained. For the manufacture of such alcoholic extracts called "triple extracts or quadruple extracts," according to their degree of concentration, the pomade or perfumed oil is well beaten up in machines called "hateuses," with cold alcohol. Actually, these machines are closed vessels fitted with mixing gear, so that the fatty material is brought into thoroughly intimate contact with the alcohol. After the extraction is complete, the alcoholic mixture is chilled to about 15°C, this having the effect of throwing out of solution any small quantities of fat or oil which may have become dissolved during the churning process; the alcoholic solution is then filtered through a small closed press, and the resulting extract is the material used by the perfumer, or, from it, can be extracted the individual constituents contained in the odour of the plant. The residual fat which has been thus exhausted with alcohol, still retains a considerable amount of odour, and is a useful material for soap makers, being sold to them under the name, of "corps épuisé."

A totally different process for the winning of the perfume of flowers first came into use about 90 years ago, and was developed into an industrial process about 1897. In this process the odorous plant material is treated with a volatile solvent

which dissolves the perfume and certain other substances, and from the resulting solution a concentrated odorous substance is obtained by evaporating off the solvent. Much knowledge is necessary in the choice of a suitable solvent, and the proper method of applying it so that the delicate aroma of a particular flower is not injured during the evaporation of the solvent. Such a solvent must dissolve the whole of the odorous constituents contained in the flowers, and it must not have any chemical action on the individual constituents; further, it is obvious that it must not leave any odorous residue, inherent to itself, on evaporation, and it must evaporate in a vacuum at temperatures so low that the most volatile odorous constituents do not distil off at the same time, and are not affected by the highest temperature required to remove the last trace of the solvent, and, of course, such a solvent must be obtainable at a price which does not prohibit its use on a large scale. It is not possible to go into any considerable details, and it may serve to mention that petroleum ether is frequently used on account of its solvent properties, and the ease with which it can be distilled and recovered. In outline, the plant material is treated in closed vessels with the petroleum ether which from time to time is drawn off and brought in contact with more of the fresh odorous plants, the process is continuous, each time the material being treated with the petroleum ether distilled off from previous extractions. Beautifully designed plants are used, having for their object the convenient handling of large bulks of raw material, the recovery of the solvent and the isolation of the odorous principles, every regard being paid to the conservation of labour, materials and heat.

The highly complex mixtures which are left after the vacuum distillation of the solvent contain a considerable quantity of extraneous matter, i.e., matter which is not odorous and which is coloured according to the nature of the flowers. Much of this extraneous matter is of a wax-like character, and some years ago the writer and J. Allan investigated the wax from the *jasmin* flower. The material had been treated for the removal of nearly all the odorous constituents and was in the form of a hard yellowish brown substance, having but a slight odour of *jasmine*. As the wax was found to contain a little alcohol, this

was removed by keeping the wax molten until no frothing was visible, after which it was used for the following examination:—

The solidifying point, as in the titer test, was between 56°C and 57°C. The examination with the Zeiss butyro-refractometer was a little difficult on account of the high melting point of the wax, but the following figures were obtained:—The scale reading at 84°C was 30; 74°, 33; 70°, 36; 65°, 38; 62°, 40; 60°, 42; 56°, 44.

It is interesting to know that Lewkowitsch gave for beeswax at 62° the reading 29.5 to 30. The acid value was determined on 5 grams of wax dissolved in a mixture of neutral alcohol and ether; it corresponded to 2.8 grams of potassium hydroxide for 1 gram of wax.

The wax was difficult to saponify, and the saponification value was determined by dissolving the substance in neutral amyl alcohol, adding alcoholic potash as usual, and boiling for five hours on a sand-bath. The final result was that 65.8 mgms. of potassium hydroxide were required per gram of wax, whilst, when using sodium ethylate for the saponification, 63 mgms. were required. The iodine value of the wax by Wijs' method was from 52 to 53 per cent.

The fatty acids were isolated from the saponified residues in the following manner: The residues were boiled with a large volume of water until all the alcohol was expelled when the unsaponifiable matter separated out as a white scum; this was skimmed off as completely as possible and was proved not to be an insoluble soap by its solubility in ether, its low melting point and the fact that it left no residue on ignition. Subsequent experiments showed that it was very difficult to remove the whole of this unsaponifiable matter from the fatty acids which were precipitated on acidifying the soapy liquor; however, by repeatedly dissolving the fatty acids in alkali, extracting with petroleum ether, and reprecipitating with acid, a hard white mass was obtained having a mean molecular weight of 398 and an iodine absorption of 39 per cent. It was not found practicable to obtain sufficient of these fatty acids to enable the titer test to be done, but when recrystallised from boiling alcohol the mixed acids melted slowly between 57° and 65° C. The unsaponifiable matter from ether yielded a mass of well-crystallised white needles,

having a sharp melting point of 64° C. On heating this unsaponifiable matter with soda-lime, hydrogen was evolved indicating the presence of alcohol, and eventually an acetyl derivative was obtained melting at 45°, but the amount was too small for analysis to be made.

The presence of such waxlike matter renders the residues from the petroleum ether extract of flowers, semi-solid or even solid and at this stage this highly odorous mixture is called "a concrete." Needless to say, they closely resemble the original delicate perfume of the flower and for this reason they are sometimes called "absolutes." There must be no misunderstanding that the preparation of such concretes is easy: in reality, it is a highly skilled operation for which the most intimate knowledge of the raw material is absolutely necessary, and the mechanical devices are also quite intricate. Once more attention must be directed to the fact that such concretes are mixed with much inodorous material, and it is very difficult to separate the odorous principles from the wax as this latter retains odour in a most tenacious manner, so that a still further process is used whereby the wax is separated and the odorous portion obtained. The exact processes used are rather largely trade secrets, but in outline the concrete is dissolved in a solvent which gives a perfect solution of both the wax and perfume substances, and to this solution is added a second liquid which throws the wax out of solution and leaves the odorous oil in solution, the mixture is then filtered and the solution distilled at as low a temperature as possible when there remains behind an oil representing the mixed perfume substances which constituted the odour of the flower, in the highest possible degree of concentration. Such flowers as the broom, carnation, cassie, jasmine, jonquil, mignonette, mimosa, narcissus, orange, rose, tuberose and violet, are treated by these processes. In this connection mention must be made of the extremely small quantities of odorous material which are actually obtainable from the flowers—in the case of the *jasmin* over 1,000 kilos of blossoms yield about 4 kilos of ordinary concrete or slightly less than 2 kilos of the absolute flower oil, whilst the *neroli bigarade*, the blossom of the bitter orange, only contains from 0.05 to 0.1 per cent. of the odorous oil and the other flowers about the

same or in some cases even less. It will be easily appreciated that floral oils prepared in this way are most costly substances and they are frequently so expensive that few perfumers can afford to use them, and this is especially true at the present time when the cost of production has so increased. It is therefore necessary for the manufacturer to offer these floral oils diluted with some inodorous material such as ethyl phthalate and the like; this is a regrettable innovation but business conditions have apparently rendered it necessary.

To return for a moment to some of the oils obtained by the steam distillation processes, neroli oil, from the flowering orange tree, requires one ton of blossom to give about 35 to 40 ozs. of the odorous oil, the red rose cultivated in the South of France needs eight to ten thousand lbs. of roses to yield about a lb. of the otto of rose, whilst the French lavender flowers give about 1 lb. of oil from every 70-80 lbs. of flowers, and 112 lbs. of the fresh English rosemary herb yields about 24 ozs. of the oil, and in the case of the red rose grown in Bulgaria, it has been estimated that 100,000 roses only give about 1 oz. of otto of rose. These figures have been quoted to illustrate the small amount of actual perfume contained in many of the odorous plants, though, of course, there are plants from which greater yields are obtainable, and this is more especially true of the plants grown in the tropics. With such costly products as the raw materials it will be appreciated that it is not every chemist who can carry out researches on the isolation of the individual constituents contained in these oils as such investigations necessitate the use and destruction of large bulks of exceedingly costly material, which must be prepared from vast quantities of raw material, and therefore research on this subject must have adequate financial assistance such as is available when large firms undertake research or by the help of the Government; and in this connection mention must be made of the work carried out by J. L. Simonsen and his staff, at the Forest Research Institute, Dehra Dun, India, and also the splendid work done at the Imperial Institute. While such work is very costly there is no doubt as to the valuable results which must result therefrom, and several firms, especially in Germany and France, have contributed largely to the

knowledge of the constituents of essential oils, and have reaped no little commercial success from the labours of their highly skilled and specialised staffs, and it is for this country to find means whereby we also shall progress in this direction.

The study of the odorous constituents of plants has occupied the attention of chemists for approximately the last 40 years, and now a great industry has arisen from their labours, viz., the artificial preparation and isolation of individual odorous organic substances which have been proved to be constituents of floral perfumes, and the quantitative determination of the individual compounds which are contained in a natural perfume, this leading to the blending of the various synthetic compounds in proportions which yield a mixture, having a more or less close resemblance to the inimitable products of nature. It is regrettable that one of the applications of the knowledge of the constituents of essential oils has been the elaboration of scientific adulteration, and this has reached such a state of perfection that the examination of essential oils for purity necessitates a very complete chemical and physical testing, not forgetting the use of a thoroughly trained nose. Still, as E. Charabot said: "the natural perfume industry and the more chemical industry of the production of synthetic odorous substances though rivals in appearance, lend each other mutual support in the path of progress on which they are both travelling, and thus there is one more instance of the truth with the fruitful instruction which it bears with it, that real continual progress, universally beneficial, is invariably shown when science and industry are bound together in close union."

THE WORSHIPFUL COMPANY OF THE WOODMONGERS AND THE COAL TRADE OF LONDON.

By HYLTON B. DALE.

The Mysterie of the Woodmongers and Coal Sellers, sometimes called the Fuellers, was of very old standing. It enjoyed its greatest prosperity in the 17th century, when it had the carmen added to it and received a Royal Charter, but fell from grace and had to surrender it 65 years later.

As early as 47, Henry III. (1263 A.D.), we hear of Alice, daughter of Peter le Wodmongere, and it is probable the

company was going in 1330, as the Coal Meters were formed in that year and the first Government tax on coal was raised in 1368 to pay for the last campaign of the Black Prince.

The "Mysterie of the Woodmongers" made its first known public appearance in 1376, when the Livery Companies were summoned to send representatives to form a Common Council to assist the Court of Aldermen in the governance of the city. The Woodmongers sent two representatives, viz.:—John Asshurst and William Schrympehniershe.

In 1306, and again in 1400, the nobility and citizens of London petitioned the King to prohibit the use of pit coal, but their petition was ineffective on both occasions in spite of a commission of Oyer and Terminer.

Coal was then chiefly used for brewing and soap making, which trades were carried on in Dowgate, and also for lime-burning, so that a sudden cold wind from the south-east filled the city with fog.

On 13th October, 1418, John Talworth and John Rephawe were sworn as Masters of the Misterie of the Woodmongers at Guildhall.

An old list of the Crafts of London, dated 9 Henry V. (1422), in the possession of the Brewers' Company, shews them 48th on the list, immediately between the Hurers and the Writers of Court Letters, and Strype tells us this was their position at the dinner to King Henry VIII. in 1532, to which they sent two representatives who wore no livery.

Furthermore, at the Court of Aldermen holden 8 July, 1518, to settle the number of Bowmen each Company should send to follow the Lord Mayor to keep the watch on the vigils of St. John and St. Peter, it was settled the Woodmongers should send two bowmen, the same number as the Cordwainers and eleven other lesser Companies.

Their first known Hall appears to have stood on the south side of Heralds' College, facing both St. Bennet's Hill and St. Peter's Hill, a short distance above the wood wharves at Paul's Wharf. (Queen Victoria Street now runs across this site.)

In 1544 they disposed of these premises and took a lease from Lord Audley of the refectory of the dissolved Priory of Holy Trinity, Aldgate.

This Priory formerly had an altar dedi-

cated to St. John the Baptist, and as he was the patron saint of the Woodmongers and for centuries a wood market had been held outside the Aldgate in Portsoken, it is probable the altar was given by the Woodmongers.

When the Chapter House, which had been turned into the Church of St. James, collapsed, the congregation had service in Woodmongers' Hall.

In 1603 the Duke of Norfolk sold the whole place to the City of London, who having new ideas as to the development of the site, terminated the Woodmongers' tenancy.

The fraternity was 70ft. by 34ft., with kitchens and offices adjoining, now covered by the Duke Street Synagogue.

Acts of Parliament, regulating the assize of wood and coals, were made in the reigns of Henry V., Edward IV., Henry VIII. and in 7 Edward VI.

On 11th October, 1580, the Court of Aldermen put under the rule and guidance of the Company all the cars and carmen of the City, and in the State Papers of 24th October, 1584, is a statement of the ancient order the Lord Mayor and Aldermen have taken for Woodmongers and of the provision of wood for London. Henry VIII. had formed the carmen into a fraternity to do away with the inconvenient right of purveyance within the City of London, and Queen Elizabeth fixed the number of carts at 400, of which 100 were to stand in Southwark, 100 on the woodwharves and 200 in Cheapside and in the outer regions of the City, each cart paying a yearly rent to Christ's Hospital.

With the accession of King James came an era of the strengthening and creation of trading companies.

The Woodmongers used the opportunity to good advantage, and on 29th August, 1605, obtained a Charter of Incorporation from the King, which confirmed all their previous privileges and placed the carmen definitely under their rule and guidance.

What weighed largely with the King was their subscription of £200 towards his fund for creating the Ulster Plantation.

They then erected a large new Hall on the river side to the east of Paul's Wharf Hill, and on 1st October, 1605, received a Grant of Arms, Thomas Hunt being the first Master and Mark Snelling and Cuthbert Coleman the Wardens.

In 1550 twenty-two ships per annum

sufficed for the supply of coal to London, but by 1615 two hundred were necessary.

The carmen were never satisfied with being amalgamated with the Woodmongers, but it took them a long time and many legal cases before they got free again.

Cromwell referred their petition to the Committee for Trade, but nothing came of it.

At the Restoration, Sir Richard Brown, the Lord Mayor who received back Charles II., happened to be a Woodmonger, and soon got all their privileges confirmed under a lease for 61 years, they giving a bond for £1,000 to Christ's Hospital.

One of the privileges granted the Grenadier Guards at the Restoration was the right to act as coal heavers in their spare time, coal-heaving being an arduous occupation requiring lusty men, and a four-hour day being sufficient for most men.

All know the famous marching song of the Guards, the British Grenadiers, and some have no doubt wondered what a tow-row, tow-row meant. The explanation is as follows :—

A gang of coal heavers consisted of 16 men, who heaved the coal up by stages from the hold and a foreman who turned the basket into the vat. Each gang had their rendezvous at a particular ale-house, and the publican, to ensure the master of a ship asking for his particular gang, would promise him a gallon of rum if he did so. This was called the tow-row. If the gang worked well and cleared the ship rapidly the master would pass the rum on to them. Hence the tow-row for the British Grenadiers.

The nick-name of the Coal Heavers still sticks to the Grenadier Guards in the Army. Four years later complaints anent the Woodmongers were rife again, and on 14th January, 1664, the House of Commons appointed a Committee to inspect the laws regulating the sale of wood, coals and other fuel, and to treat with the Lord Mayor and examine grievances concerning retailers enhancing the prices of coals.

On 2nd March an Act was passed regulating the Assize and Measure of Wood and Coals. The minutes of the Court of Common Council tell us a lot about the proceedings, and there are long petitions both from the Carmen and the Woodmongers.

On 17th February, 1664-5, the Woodmongers handed back their lease for 61 years, receiving a cancellation of their bond, and an Act of Common Council, 21st June, 1665, took away their government of the

cars and carmen, and ordered sea coals to be sold only in sea coal meter's sacks and prohibiting the Woodmongers from keeping any carts of their own, but compelling them to use the public cars.

The City Companies were ordered to store in their halls a quantity of coal in the summer to be sold cheap to the poor in winter, the quantity varying from 672 chaldron (25½ cwt.) in the case of the Mercers to as low as three chaldron in that of the Bowyers and Fletchers.

Whatever happened in the case of the small men, the Woodmongers in a large way continued to employ their own carts and ignored the Order of the Common Council.

All through the Plague their carts added to their usual duties the unpleasant one of carting away the dead. Sir Edmund Bury Godfrey, the Woodmonger of Westminster, was particularly active in this, and was eventually knighted by the King for his brave efforts.

Large public fires of coal were burned in the principal streets, because the doctors said this helped to clear the air of infection. About 200 chaldron a week were burned in this way.

The fleet of colliers was kept back at Deptford, and the woodmongers had to send their lighters down there to fetch the coal.

Then came the Great Fire of London, and the Woodmongers' Hall was utterly consumed, together with 20 wharves of wood and coals, value £20,000, and carts and gear. The Woodmongers were so busy salvaging the goods of others, charging as much as £40 for a cart, that they appear to have neglected looking after their own property until too late.

To add to the trouble, the country was at war with the Dutch, and the winter of 1666 was the most severe ever known.

On 8th December, Pepys writes: "In much fear of ill news of our colliers, a fleet of two hundred sail and fourteen Dutch men of war between them and us and they coming home with small convoy and the City in great want, coals being at three guineas per chaldron." And again in March, 1667: "Everybody now complains of the dearness of coals, being at £4 per chaldron, the weather being most bitter cold, so that the King said to-day it was the coldest day he ever knew in England."

Sir Edmund Bury Godfrey had been extremely busy trying to subdue the Great

Fire and the King presented him with a special silver cup in recognition of his efforts. When the weather grew milder things became somewhat better, for in April, 1667, Pepys writes: "To-day I got in some coals at 23s. per chaldron, a good hearing I thank God, having not been put to buy coal all this dear time, that during the war poor people have been forced to give 45s. and 50s. and £3."

However, the war continued, and with it the troubles of the Woodmongers. In the Domestic Papers, 5th July, 1667, we find: "Arrival of 60 sail of colliers; 200 more sailed with them without convoy, but have put into Llynn. The coals will be carried from Llynn to London. The price is 30s., the chaldron, water carriage to Cambridge will be 4s., cartage thence to Ware 20s., or 25s., water carriage, Ware to London, 6s. or 7s. per chaldron."

As usual the public were quite unable to realize the troubles of the coal merchant. All they knew was that coal was extremely dear and they threw all the blame on the Woodmongers and demanded a public enquiry, which was duly held.

Mr. Pepys, cousin of the diarist, formed one of the investigating committee who reported that the principal cause of the present extraordinary price of sea coals was the want of a sufficient convoy last summer to guard the colliers, and the pressing of their able seamen. They, therefore, recommended the Crown to grant protection to the seamen.

The report was adopted by the House by 69 votes to 47.

On 14th October, 1667, a Bill was introduced to prevent extortion and abuse in the sale of coal and wood, and was referred to a Committee instructed to send for the Patent of the Woodmongers and consider the laws in force against them and provide for the effectual putting of them in execution.

However, the Woodmongers appear to have been truculent, so the Clerk was ordered to be sent for in the custody of the Sergeant-at-Arms and the Master to attend the House to-morrow with the Charter and books of the Company.

The Master duly appeared with his petition, but on 6th November judgment was given: "It is resolved that this House do agree with the Committee that the Charter incorporating the Woodmongers with the Carmen is illegal. That the said Charter is a grievance to His Majesty's

people and not to be continued. That coals and wood should be sold at easy rates."

Consequently, on 5th December, 1667, Sir Edmund Berry Godfrey, the Master, and Francis Baleh and Wm. Maibrin, the Wardens, surrendered the Charter before Sir Walter Littleton, Master in Chancery, the record being duly made in Latin of a very doggy nature.

Woodmongers' Hall was not rebuilt after the fire, as it was settled to have a broad quay, 40 feet wide, all the way from the Tower to the Temple, raised three feet to avoid inundation, and pushed out some way into the river. (In fact, this open quay existed for 100 years, and not until the 19th century did folk dare to encroach on it with cranes, sheds and houses, the City winking a blind eye, and Parliament, in 1821, ill-advisedly passing a short Act exonerating the offenders.)

It had been a very ancient location for the trade in wood for as early as 29 Edward I. St. Bennet's is called St. Benedict del Wodewharf, and in 14 Edward II. we come across the Wodehawe there.

The disputed cases as to tenures, which for 10 years after the fire engaged the attention of the judges, contain nothing concerning the Woodmongers' Company, although there are two cases referring to individual woodmongers in Thames Street and on Puddle Dock Hill.

Where the Woodmongers held their Hall after this is not clear. My own idea is they had rooms near the Dog Tavern, opposite the Customs House. There is nothing in Oliver and Mills' survey.

In the Additional Building Act, the Lords tried to insert a clause that the sites of St. Magnus the Martyr, St. Botolph, Billingsgate, St. Michael, Queenhithe, and All Hallows the Great and Less, should be converted into public store-yards for coal and other fuel, but this was not accepted.

Sir Christopher Wren, in his plan for rebuilding London, wisely provided for a great wood wharf to the east of the junction of the Fleet with the Thames, with a site for their Hall next Bridewell Dock. But the City, in their wisdom, bearing in mind that the site for the coal trade from the earliest times had been higher up the Fleet next Sea Coal Lane, which is mentioned in the Pipe Rolls as early as 1228, determined to canalise the Fleet at a cost of £80,352, and erect large coal vaults along

it with a large hollow square to the east entered from Sea Coal Lane, in which the carts could comfortably stand. These survived until 1734, when the river from Holborn Bridge to Fleet Bridge was arched over and the Fleet Market House erected over it by George Dance the elder, the remainder of the Fleet remaining open until 1765.

But the City were wrong in expecting it to become the chief centre of the trade. Only the smaller merchants went there, as boats could only come up at high tide, and even then had to pass three bridges. The larger merchants preferred to be in the River Thames. There was a coal meters office in Durham House Yard, where the premises of the Royal Society of Arts now are, and woodwharves between Somerset House and Arundel House Garden and at the foot of Milford Lane, and also at the foot of Water Lane.

A clause was added to the Act for rebuilding the City, raising the coal tax to 1s. per chaldron, but the trade was so disorganised that this produced but a small increase, so in 1670 it was boldly raised to 3s. per chaldron.

It was coal which paid for the straightening and widening of the streets, for levelling the contours, erecting the wharves, canalising the Fleet, for markets, Bridewell and other prisons, for all the Wren city churches, even for St. Paul's Cathedral, all of which money passed through the hands of the Woodmongers, who, in spite of the surrender of their Charter, remained a powerful body. The City dues were raised to 1s. 2d. per chaldron in 1687 and so remained until 1831, when they were reduced to 1s. 1d. per ton. In those days 136 Newcastle chaldrons equalled 217 of London.

Pepys tells us that in May, 1669, Sir Edmund Berry Godfrey dared to arrest for a debt for coals the King's physician, Sir Alexander Frazer, within the royal precincts of Whitehall, which made the King so angry he had the bailiffs severely whipped and put in prison in the Porter's Lodge, where he also imprisoned the worthy knight, who, however, went on hunger strike, and had to be released.

In 1673 a Bill was introduced into Parliament for the better regulation of the coal trade, but Parliament was prorogued before it could be passed, so the King wrote and instructed the Lord Mayor to appoint a Committee with a view to an Act of Common

Council being passed. They drew up their Order, but the Woodmongers refused to be bound by the rule they should have no carts of their own, and took the matter before the judges, where it hung about from Court to Court for years, until in 1679 the Court declared the Act was illegal and a monopoly.

The Woodmongers put forward many reasonable suggestions. Nevertheless, in October, 1680, the Committee for the Markets made a new Act, fixing the total number of carts for the City as 420 and putting them all under the oversight and government of Christ's Hospital, the arms of the City to be on the shaft of each cart, and refusing any carts to the Woodmongers who, when they sold coal, were to be compelled to send for a public cart and send along with it a sealed bushel for measuring the coals if need be, which might only be sent in sea coal meters sacks.

Meanwhile, the Woodmongers had been in the limelight, for in September, 1678, Titus Oates brought to Sir Edmund Berry Godfrey his narrative of the Popish Plot. Six weeks later the worthy knight disappeared and was found murdered on Primrose Hill. Medals were struck, showing the murder. Three men were tried and hanged at Tyburn. Samuel Pepys' servant, Samuel Atkins, was accused of being an accessory before the act, but was acquitted, Pepys himself writing out his defence.

The Woodmongers stuck to their ideas, and in 1681 the judges gave directions how the Act should be amended. The Carmen, who had formed themselves again into a fraternity (which still exists and led off the last Lord Mayor's Show) with three Wardens and 20 Assistants, a Clerk and a Beadle, offered in addition to the £400 payable annually to Christ's Hospital, to pay £400 to the City and to make and maintain a cartway up and down Tower Dock if they were left with a monopoly.

For 13 years more the controversy dragged on, until in October, 1694, the City passed a fresh Act, allowing the Woodmongers 120 carts of their own, to be used only for carrying coal and fuel, to be burned with a faggot mark on both sides, and the raves of the carts to be higher than those of the street carts the better to distinguish them and to keep the coal from falling off. This type of cart continued in use up to 1865, when the present type of van was invented.

A list of such carts and their owners

was to be made each year in May for the Lord Mayor and Aldermen.

Thus the Woodmongers once more came into their own.

In 1694 the metage was raised from 4*d.* to 8*d.* per chaldron, and Orphans' Dues of 6*d.* per chaldron were created, which were not liquidated until 1782, and continued as the coal dues to our own era, being utilised for City improvements.

The Woodmongers' triumph was short-lived. Six years later a much more dangerous event occurred.

On 29th September, 1700, an Act of Parliament was passed which amalgamated the Watermen and Lightermen into one large Company and prohibited any but those registered by the Company from working boats on the Thames.

The Company promptly started to oppress the Woodmongers by refusing to register them as Lightermen, which led to a petition being sent to Parliament, but the evil practices continued, until in 1730 they led to a series of petitions and broadsides and to an enquiry which resulted in a new Act, empowering all persons having wharves for the sale of coal to keep and employ their own lighters, but to enter them on the books of the Watermen's Company and to employ properly qualified men registered at Watermen's Hall. Twelve Lightermen then handled half the coal coming to London, 40 others handling the other half.

In January, 1740, the Thames was frozen over and coal rose to £3 10*s.* per chaldron.

Orphans' Dues were given an extension in 1748.

In 1758 the trade was greatly disturbed by the pressing of men for the Navy, 800 being impressed on 22nd June.

By that date the Woodmongers' Company would appear to have died of inanition. Many of its members and their sons being freemen of the Watermen's Company, no longer saw any necessity for belonging to another Company. Yet the Watermen's Company embraced many others who were not interested in coal.

To get over this difficulty and to unite both parties, the Society of Coal Merchants would appear to have been created in 1731, which took over as an inheritance the duties of the Woodmongers' Company.

As to the date when the last Freeman of the Company was admitted I cannot say, but the title still persisted, and as late as the enquiry of 1830, we find a witness

declaring he was a Woodmonger, but his son was a Lighterman and had served seven years to the oar.

In May, 1758, we find the Coal Heavers petitioning Parliament anent the Coal Undertakers, a class of men who had created their own Labour Bureau and had purchased a monopoly of the coal shovels, which they purchased at 3*s.* 6*d.* each and hired out at 1*s.* the time.

The House appointed a Committee to investigate, and on one of the Undertakers threatening a Coal Heaver ordered him to appear on his bended knees at the Bar of the House.

An Act was passed in June, 1758, for the better regulation of the Coal Heavers and to enable them to create a Benevolent Association.

In 1763 the Thames again froze and coal rose to £2 15*s.* per chaldron.

In 1767 Orphans' Dues were again extended, and the Coal Merchants obtained an Act to establish Land Meters and make a charge for the measuring into sacks from the barges between the Tower and Limehouse Hole. The harvest failed the same year and the cost of living rose accordingly, and led to grave riots among the Coal Heavers, which, coupled with Wilkes and Liberty, resulted in the St. George's riots terrorising London in the following April, May and June, until the military were called out, and eventually two of the culprits were hung at Tyburn and seven more in Sun Tavern Fields. The rioters were largely Irishmen. They put in another petition to Parliament the following March, blaming the Coal Undertakers again. In 1768 the Coal Exchange was erected in Lower Thames Street.

The Government tax on coal was steadily rising about this time, being 8*s.* per chaldron in 1775, and 9*s.* 4*d.* in 1798.

Up to 1786 the Coal Heavers worked in gangs of 16, with a master, but a new system was then introduced by which the coal, instead of being shovelled up by stages to the vat, was whipped up whippers in a basket and the gang reduced to eight men, four of whom shovelled while four whipped the basket up by ropes on a pulley, and the foreman as basket man turned the basket over into the vat. This was a great improvement.

In 1788 an Act was passed prohibiting any number of persons exceeding five from uniting for the purchase of coal.

In 1786 the Coal Buyers Indemnity Act had relieved the merchants from the responsibility for weight and put it on the Land Meters, who had started first of all in Westminster and been introduced into London in 1734, and who were on duty from 5 a.m. to 9 p.m., with no recognised breaks for meals.

In 1797 the Expedition to Holland took away a large number of the ships and upset the coal trade with the usual results and outcry. An enquiry was held in the Lords, followed in 1800 before a Committee of the Commons, on which sat Mr. Pitt, Mr. Wilberforce, Sir Matthew White Ridley, the Lord Mayor and others.

As a result it was decided to buy out for £25,600 the Coal Exchange, which had been erected privately in 1768 in Lower Thames Street, to charge every ship arriving with coals a penny per chaldron to pay for the purchase, to throw the Exchange and Trade open to everyone and put it under the care of a Committee of the City, presided over by an Alderman.

The individual societies of factors and merchants and the privileges of the Watermen, nevertheless, continued to exist.

In 1805 an Act was passed enabling coal to be brought to London by the Grand Junction and Paddington Canals up to 50,000 tons a year, paying 1s. 2d. per ton duty plus the market penny.

In August, 1807, there was a fresh Act of Parliament, by which nine coals only were allowed to be sold as Best Coals, but might be mixed, and three sorts were allowed to be mixed and sold as one or the other, but no other coals might be mixed, and compelling all coals ex-ship to be sold on the market only, 21 chaldron to be the minimum sale there. A fine of £20 per chaldron was imposed for selling one coal in place of another. No man was allowed to act as a Coal Undertaker without a licence from the Corporation, and no licensed victualler to be a Coal Undertaker. Shovels and baskets were to be found by the ship's master. The Undertaker was to be allowed 1d. per chaldron.

In 1807 the old Act empowering the Court of Aldermen to fix the price of coal was repealed, and in 1809 the Government tax was raised to 12s. 6d. per chaldron, and so continued to 1815, when it was reduced to 9s. 4d.

The system of the Ingrain, by which the colliery owner gave 21 chaldron and charged

it as 20 (the score) applied to the south only, the ship owner reckoning freight on the same basis. Suffolk, Essex, Middlesex, Surrey and Kent were the counties affected. A purchaser of 5 chaldron had the ingrain passed on to him. Smaller purchasers had an adjustment made in the price. Its origin very likely came from an attempt to compensate the customer for the payment of the coal dues, coupled with the knowledge that coal was lost in loading and unloading the ship and loss from slates.

In 1827 6,883 ships came to London with coal, averaging about 300 tons each.

In 1814 only 2,707 chaldron were coming by canal.

In 1824 the Government tax was reduced to 6s. the chaldron, and in the next three years the price of coal fell from 46s. to 36s. 6d.

In 1827 the coal merchants and others were writing to Parliament, complaining of the very unsatisfactory nature of the coal meters, and also about the Coal Tax.

This eventually led to a general enquiry into the whole trade, first before the Lords and then before the Commons.

The evidence given very clearly shows the manner in which the trade was conducted. Thus, Wm. Horne said he employed four horse wains carrying 2½ chaldron at a time. If anyone ordered 2½ chaldron or more they got the ingrain, if less an adjustment was made in the price. All cartage was averaged and charged at 6s. per chaldron plus 1s. 6d. per chaldron for shooting the coal and 1s. per five chaldron for trimming.

The carmen did 8½ chaldron per day. He only paid one man, but two always went with the wain, and sometimes they took a third. The wages were 9s. per week for driving and attending the horses and 9d. per chaldron for the coal. The average cartage was 1½ miles and the charge made was for deliveries "on the stones," extra being charged on bad roads.

The carmen did an average of 3½ journeys a day over the year of 300 days.

The loaders were paid 1s. per chaldron and worked in gangs of five, of whom three shovelled and two stowed the sacks, the carmen paying them 3d. per chaldron for the stowing. The loaders earned 7s. to 8s. per day and the carmen's wages worked out at 6s. 9½d. per day.

The merchants generally took a day off on Thursdays.

Their profit on sales was very moderate.

being about £1 on 52 chaldron, and they reckoned to make their real profits out of their discounts and ingrain and on working their barges and cartage well.

Where credit extended over more than two months they charged 2s. per chaldron extra. Bills were usually paid once a year. Wages had advanced in 1810 owing to the high cost of provisions, but were reduced again in 1824 and were now overdue for a further reduction.

There were 19 houses of coal factors and 10 of first buyers who took the whole contents of a ship and who sold to the second buyers, representing some 60 other firms, at 1s. per chaldron commission. A first coal buyer would have room for some 2,000 chaldron on his wharf.

The result of the enquiry was an Act of Parliament which revolutionised the coal trade.

Sea coal meters were done away with for seven years and land meters were abolished.

Coal was to be sold by weight and not by measure.

A customer was to be allowed to make the carman weigh the whole load instead of one sack in the presence of a police constable, and the merchant was robbed of his right of being notified before the weighing took place.

The poor lost their right of receiving the coal which henceforth was not to be forfeited.

Coal must be delivered in sacks, each containing 1 cwt. or 2 cwt. or else in bulk.

The Government tax of 6s. was entirely abolished.

The City dues were altered from 1s. 2d. per chaldron to 1s. per ton plus 1d. for the expenses of the Coal Exchange.

Any Lighterman might enter into partnership with any Woodmonger solely for trade in coal.

The Act, of course, entirely disorganised the trade. Those in the trade felt it very awkward, there was no independent person to judge between buyer and seller. Consequently the Society of Coal Factors and the Society of Owners of Coal Craft subscribed money between them for a Coal Meters' Society, under a deed of trust, and engaged a clerk to license meters, the City Authorities lending their late clerk to instruct him in his duties, with a Committee formed half of factors and half of merchants, with a different President every month. It

was so efficient and simple that the City never resumed its duties, and the Society of Owners of Coal Craft having changed its style to the Society of Coal Merchants in 1836, the latter Society finds the members of half the Committee, which are now reduced to six aside. Both parties pledged themselves to employ only meters licensed by the Clerk.

When the enquiry into the City Companies was held 1826-1828, a summons was sent to the Woodmongers, but no one appeared.

Acts of Parliament for long after continued to style Coal Merchants as Woodmongers, however.

OBITUARY.

SIR LANCELOT HARE, K.C.S.I., C.I.E.—Sir Lancelot Hare, a distinguished Indian Administrator and Lieutenant-Governor of Eastern Bengal and Assam, from 1906 to 1911, died on October 7th at his residence in Embankment Gardens, Chelsea. Born in 1851 he was a son of Thomas Hare, Benchet of the Inner Temple, political reformer, and father of Proportional Representation. He was educated at St. John's College, Hurstpierpoint, and the City of London School. He passed the Indian Civil Service Examination of 1871 and was posted to Bengal, where, after the usual period of probation, he arrived, in 1873, during Sir George Campbell's governorship. Among the posts he successively filled were those of Officiating Inspector-General of Police, Assam (1880), Commissioner of Patna (1900), and Chief Secretary to the Bengal Government (1903). In 1904, upon the nomination of the late Sir A. H. L. Fraser, he became a member of the Bengal Board of Revenue—one of the coveted prizes of the Service—and was also given a seat in the Provincial Legislative Council. In 1906, while acting as Lieutenant-Governor of Bengal in Sir A. Fraser's absence on leave, he was chosen to succeed Sir Bampfylde Fuller as head of the administration in the newly-created Province of Eastern Bengal and Assam. Throughout his term of office as Lieutenant-Governor he was beset by very formidable difficulties arising from the extreme unpopularity of "partition," or, as Lord George Hamilton described it at the Royal Society of Arts when Sir James Bourdillon read a paper on the subject, "The duplication of administrative machinery."

Sir Lancelot joined the Society twenty-two years ago and was actively interested in the work of the Indian Section, attending most of its meetings and sometimes taking part in the discussions. Economics attracted him and he

was one of the speakers at the Sixteenth Ordinary Meeting on March 15th last, when Mr. Oswald T. Falk, C.B.E., read his paper on the problem of exchange stabilisation. Sir Lancelot had himself a few months earlier written a work entitled "A Study of Exchange." He was also the author of a pamphlet on "The Transferable Vote System."

INDUSTRIAL CONDITIONS IN NORWAY.

Norway is in some respects one of the most interesting countries in Europe. The area round Christiania is the most highly industrialised. But the conditions in the west of Norway are quite exceptional by reason of the small and scattered population, and the broken and mountainous country rendering communication difficult. With its long coastline it has naturally great maritime interests. Prior to the war Norway stood fourth amongst the countries of the world in respect of mercantile marine, with a total tonnage of about 2,800,000. The proportion born by its commercial fleet to population was higher than that of any other country. Nearly half the shipping was destroyed during the war, yet by 1921 it had already attained its former value.

As is well known, there are great fishing centres off the western coast, notably at the Lofoden Islands. In good years the total value of the fishery products has reached £5,500,000. The fish market in Bergen is a famous sight for visitors, but generally speaking, not much is seen of this activity by the tourist who visits this part. He is more concerned with the pastoral life of the people in the fiords, whose livelihood depends mainly on their cattle, and especially their famous and varied kinds of cheese. Every visitor to Norway is aware of the scanty growth of grass at the foot of the cliffs, which has led to the practice of sending the cattle up to "saeters" a thousand or more feet up, where they can feed on the upper grass, whilst that in the valley is cut and stored for the winter.

The next impression received by visitors is the marvellous growth of trees in the humid Norwegian climate, often growing out of imperceptible crevices in the rock lining the fiords. Houses are invariably constructed of wood, and in their fresh coats of paint make a charming sight perched at intervals up the steep hills. There is said to be upwards of 26,640 square miles of forest area in Norway, about 60% being pine and fir. Exports of forest products have reached £8,000,000 in some years, an important element being the supplies of wood pulp. The Norwegian Afforestation Association is responsible for the upkeep of these forests, 10 to 15 million trees being planted annually.

A third consideration of interest is the general use of electricity. Norway has no coal of its own and derives about 25% of her imports

of this commodity from Spitzbergen. The cost is naturally high. Fortunately, the country is unique in its abundant and conveniently situated water power, from which electricity is almost exclusively obtained. The potential water power has been estimated at 15 million h.p., of which the State owns about two million. The great advance in the use of electricity is illustrated by the fact that in 1907 only 250,000 h.p. had been developed, while by 1913 the figure had risen to 750,000 h.p., and by 1920 to 1,200,000 h.p. This development of electric power has had a marvellous influence on the industries of Norway, bringing into existence new sources of revenue. The position of local industries is often decided by the site of electrical generating stations, situated in delightful surroundings amidst the hills, and without any of the smoke and refuse which one associates with stations in England. Hydro-electric developments have led naturally to the initiation of carbide, aluminium and artificial nitrate works. Norway is not a rich mining country, most of the ore being of relatively poor grade. But electrical smelting will make possible the treatment *in situ* of ores which would otherwise be exported in the crude state, or possibly would not pay for development. A scheme is now on foot for supplying electric power to Denmark, and possibly ultimately to Germany. Electrically driven flour and textile mills, each with its colony of picturesque wooden cottages for workers, are found in most unexpected places.

Yet another form of local industry in which Norway excels is the production of hand-woven mats and carpets, work on which is undertaken mainly in the winter months when there are no English visitors to distract attention. At the Hotel Mundal, at Fjaerland, where the greatest glaciers in Europe descend from the Jostedal snowfield to the foot of the fiord, there is a workshop of this kind. Here some delightful work is done under the supervision of Brita Mundal.

Few people realise the small population of Norway—little more than 2½ million people. The population of Christiania, its capital, is only about a quarter of a million, and of Bergen, the next biggest town, about 90,000. Norwegians, however small in number, are an industrious race with varied interests, friendly and hospitable disposition and a general resemblance to the British, for whom they have a traditional liking. The blending of pastoral life and industry is one of the happiest features of Norway. English is a compulsory subject in the schools, with the result that things are made easy for the British visitor. It is interesting to recall that the leading travel bureau for Norway is associated with the name of an Englishman, Bennett, who has thus been the means of introducing many of his countrymen to the delights of Norwegian scenery.

FRIDAY, OCTOBER 27, 1922.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C. (2)

NOTICES.

OPENING OF THE 169th SESSION.

The opening meeting of the 169th Session will be held on Wednesday, November 8th, when an address will be delivered by LORD ASKWITH, K.C.B., D.C.L., Chairman of the Council, on "The Value of Strikes and Lock-outs." The Chair will be taken at 8 p.m.

ARRANGEMENTS FOR SESSION 1922-23.

Particulars of the arrangements for the forthcoming session, so far as they are at present completed, are in course of issue to all Fellows of the Society.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

THE CONSTITUENTS OF ESSENTIAL OILS.

By LIONEL GUY RADCLIFFE, M.Sc.Tech., F.I.C.

LECTURE II.—*Delivered March 27th, 1922.*

THE CLASSIFICATION OF THE CONSTITUENTS OF ESSENTIAL OILS.

In general essential oils may be regarded as consisting of two main ingredients—the first of these is a terpene or a mixture of terpenes, whilst the other ingredient is a more or less complex mixture of other chemical compounds, and the individual members of this mixture may include any of the more common classes known to organic chemistry. In some oils the terpene is the most important component, but this is seldom the case when the main use of the essential oil is on account of its characteristic odour. The terpenes are compounds com-

posed of carbon and hydrogen only, and this term was first given to them by Kekulé, and he also showed the relationship between the hydrocarbon cymene (methyl para isopropyl, benzene) and the terpenes as a group. Of the oils in which terpenes predominate, the best known is the familiar liquid turpentine, and Kekulé by treating this with iodine obtained the fundamental hydrocarbon cymene. There are the usual three isomeric forms of cymene:—

and from these cymenes most of the various terpenes can be obtained. Cymenes are to be regarded as the parent substances of the terpenes, with the exception of certain terpenes of which pinene, camphene and fenchene are the chief. Para cymene is the most important one of the three, giving rise to such terpenes as limonene, dipentene and terpinolene, whilst meta cymene is the parent substance of sylvestrene and carvyltrene.

To understand these relationships it must be borne in mind that those hydrocarbons which have the empirical formula C_5H_8 are termed terpenes, and of these there are four main classes:—

The aliphatic or olefinic terpene alcohols and aldehydes. The compounds to be dealt with exhibit amongst themselves a certain similarity of structure, and at the same time show a definite connection with the terpenes proper. The substances themselves occur in essential oils in large proportions and are responsible, in many cases, for the delicate and characteristic aroma of the oils in which they occur. Their chemical structure is such that they contain 10 carbon atoms arranged in such a way that 6 of these form a straight chain, 3 of the remainder are in the form of an unsaturated isopropyl group attached to one end of the chain, whilst the tenth remaining carbon atom is a methyl group attached to the fourth carbon atom from the end of the chain. Actually the grouping may be regarded as resembling that of a monocyclic terpene in which the ring has been broken, and this conception is not a purely fanciful or theoretical one, for cyclic terpene can be obtained by quite simple methods from these olefinic straight chain compounds, and by a reversal of the process several cyclic compounds may be converted into open chain members of the aliphatic terpene group.

TABLE.

this is a stereo-isomer of geraniol and each of the two give aldehydes on oxidation.

Geraniol when oxidised yields α citral, also called geranial—

whilst the nerol gives β citral or neral—

from citronellol there is obtained the aldehyde citronellal—

The relationship of the above compounds to the terpenes can be shown as follows:—When citronellal is heated with acetic anhydride it changes into the alcohol isopulegol and this on oxidation becomes isopulegone—

The resulting isopulegone when treated with baryta water, undergoes an isomeric change into pulegone:—

As another example, linalol:—

treated with formic acid yields a mixture of terpin and dipentene. In the first place, it appears probable that the linalol undergoes an isomeric change into geraniol—

and this, by the removal of water from one part of its formula, and the subsequent addition of the elements of water to another part of its structure gives, as a first result, ring formation and terpin, from which a loss of water results in dipentene:—

This brief outline will be sufficient for the comprehension of the relationships of the

aliphatic terpene derivatives. In addition to the aliphatic terpenes there are also the aliphatic sesquiterpenes and their derivatives, of which a brief mention must be made. Sesqui-citronellene $\text{C}_{15}\text{H}_{24}$, is an example of an aliphatic sesquiterpene with two conjugated double bonds and is isomeric with ocimene; it was isolated from Java citronella oil by Semmler and Spornitz. In 1904, Soden and Treff and Haarmann and Reimer discovered an aliphatic sesquiterpene alcohol called Farnesol, in various acacia oils, and otto of rose, musk seed oil, and lime blossom oil. There are corresponding aldehydes and acids, whilst "Dorenone" is an aliphatic sesquiterpene ketone, discovered in oil of gum ammoniacum.

Returning now to the cyclic terpenes--the terpenes proper may be divided into two large groups in which the hydrocarbons of the first group contain one ethylene linkage, whilst those of the second group contain two such linkages. As a class, the terpenes may be regarded as hydro-cymenes, and though hexa hydrocymene does not occur in essential oils, there are oxygen containing compounds corresponding to it which are very widely distributed in nature, e.g., oil of peppermint contains the alcohol menthol $\text{C}_{10}\text{H}_{19}\text{OH}$, and the ketone menthone $\text{C}_{10}\text{H}_{18}\text{O}$. Two compounds, carvo-menthone $\text{C}_{10}\text{H}_{18}\text{O}$ and carvo-menthol, (tetra-hydrocarveol) $\text{C}_{10}\text{H}_{19}\text{OH}$, structural isomerides of the other two, are to be considered as a completely hydrogenated parent substances of a considerable number of unsaturated oxygenated members of the terpene group, though they themselves have not been found in essential oils. If one molecule of water be eliminated from menthol or carvo-menthol, isomeric hydrocarbons of the formula $\text{C}_{10}\text{H}_{18}$ are formed which may be considered to be structural isomerides of tetra hydro-cymene. The following table will illustrate these relationships —

Hexa hydrocymene, terpane, menthane

In accordance with our present knowledge of the terpenes which is partly derived from their optical activity, molecular refraction and magnetic rotation, they

may be separated into a monocyclic and a bicyclic group. The first group of monocyclic terpenes also called menthadienes, may be regarded as dihydro derivatives of para and meta cymene, or expressed in another way, as unsaturated derivatives of hexa hydrocymene, i.e., menthane. For purposes of nomenclature, the latter view is adopted, and the members of the group are described as menthadienes, i.e., menthane with two double linkages, and the positions of these linkages is indicated by the use of the Greek capital Δ , in conjunction with the usual method of numbering the benzene ring:—

The second group includes the bicyclic terpenes and shows, as a class, a characteristic behaviour when a member is submitted to certain chemical treatment, inasmuch as such terpenes can only unite with one molecule of a halogen or of a halide acid, and for this and other reasons, they are assumed to have what is called a "bridged ring" structure. These bridged rings are now recognised as the basis of the second group, and corresponding to such compounds are saturated hydrocarbons of the formula $\text{C}_{10}\text{H}_{18}$, e.g., camphane

It has already been pointed out that all the terpenes are unsaturated compounds, but distinct differences are shown in the respective capabilities of different terpenes to combine with the halogen acids, and this

property is most useful for the recognition of the individual members. For example, the bicyclic terpene, pinene, which forms the major portion of oil of turpentine, on treatment with dry hydrochloric gas in a freezing mixture yields a solid saturated compound—the result of the addition of one molecule of hydrochloric acid—the compound being called pinene mono-hydrochloride $C_{10}H_{16} \cdot HCl$; this is a camphor-like mass and has been called “artificial camphor,” and can be crystallised from alcohol when it melts at 125° and is so stable that it distils almost unchanged between 207° – 208° . If this hydrochloride is heated with aniline, the hydrochloric acid is removed and another terpene, camphene, is produced. This camphene can itself absorb a molecule of hydrochloric acid, and yields a similar mono-chloride which resembles that from pinene except that it melts at 151° , and there is also a difference in its stability. The monocyclic terpenes or menthadienes, dipentene and terpinene, combine with two molecules of hydrochloric acid, each yielding the same compound, a dihydrochloride $C_{10}H_{16} \cdot 2HCl$, of which there are cis and trans varieties. Sylvestrene, which occurs in Swedish pine oil, is a terpene derived from meta cymene, and yields a dihydrochloride melting at 72° , whilst the purely synthetic terpene, carvestrene, also a meta compound, yields a dihydrochloride melting at 52° .

The addition of bromine to the various classes of terpenes gives rise to bromine addition compounds which play an important part in the recognition of the terpenes. In general, the reaction is conducted by brominating the terpene in nearly glacial acetic acid solution and then recrystallising the products from acetic ether. By this means the two large terpene groups are distinguished, the members of the first group containing one ethylene linkage are only able to add on one molecule of the halogen, whilst the members of the second, with two ethylene linkages, take up two molecules of the bromine, for example, bicyclic terpenes, such as pinene combine directly with bromine yielding a crystalline dibromide $C_{10}H_{16}Br_2$, which melts at 169° – 170° , and when heated with aniline yields para. cymene; on the other hand, a monocyclic terpene, such as limonene, absorbs bromine forming a tetrabromide melting at 104° – 105° , and the other menthadienes also yield tetrabromides.

Another very important means available for the identification of the individual terpenes, is the study of the compounds which they form with the oxides of nitrogen and their derivatives. The first experiments made by Cahours, 1842, on the formation of the nitrites formerly called nitrosiles and also nitrosites, resulted in the production of phellandrene nitrite $C_{10}H_{16}N_2O_3$; of this there are alpha and beta modifications which also exist as cis and trans forms; from the alpha phellandrene nitrite, one melts at 112° – 113° , and the other melts at 105° ; whilst the β phellandrene nitrite also yields two modifications, one melting at 102° and the other at 98° . As an outline of the method used, the phellandrene, in ligroine solution, is treated with aqueous sodium nitrite and then dilute acetic acid added, whereupon the nitrite separates out as a crystalline substance.

In 1874, Tilden discovered that certain terpenes reacted with nitrosyl chloride $NOCl$. Originally the experiment was carried out in the following way: in the first place nitrosyl chloride was made—the nitrous fumes generated by the action of nitric acid upon arsenious oxide are passed into well-cooled strong sulphuric acid, when crystals of nitrosyl sulphate gradually separate out, these are mixed with dry sodium chloride and gently distilled, when nitrosyl chloride distils over and can be dissolved in petroleum spirit; the solution is then added to the terpene, for example, pinene gives at first a fine blue colouration, which persists for some time if the mixture is kept cool, but fades later on. This mixture, containing the nitroso chloride, is diluted with alcohol, which results in the formation of a white crystalline precipitate of pinene nitroso-chloride, having the formula—

Such nitroso-chlorides are decomposed by treatment with aniline or with dimethyl aniline, giving respectively a diazo com-

pound or a nitroso compound and the hydrocarbon is regenerated: this is very interesting, because it is the only case in which pinene can be recovered from a compound unchanged in constitution. Instead of using the specially prepared nitrosyl chloride, O. Wallach found that an alkyl nitrite, such as amyl or ethyl nitrite and hydrochloric acid, could be used when added to the terpene in glacial acetic acid solution:—

To illustrate the practical utility of this reaction one may take the examination of oil of orange peel for adulteration with turpentine. The essential oil is carefully distilled, and any portion coming over below 170°C should not yield pinene nitroso chloride and nitroso pinene (derived from added oil of turpentine). The test is conducted thus:—

Dissolve 5 c.c. of the fraction to be tested in one half its volume of glacial acetic acid, add 5 c.c. of amyl nitrite, cool thoroughly in a freezing mixture and add very gradually 5 c.c. of a mixture of equal volumes of hydrochloric acid and acetic acid. Collect any crystals which separate from the blue or greenish liquid by filtering them off at the pump and washing them with a few drops of alcohol; these will be the pinene nitroso-chloride. Transfer the crystals to a small flask, add 5 c.c. of an alcoholic solution of caustic potash and heat the mixture on a water bath for 15 minutes, then pour the solution into ice cold water, filter off the crystals and wash them with water. Dry these crystals on a porous tile and re-crystallise them from alcohol and then determine their melting point. Pinene nitroso-chloride, as usually obtained, melts at 103°, but crystallisation from alcohol raises the melting point to 115°. When the nitroso-chloride is treated with the alcoholic potash, nitroso-pinene $C_{10}H_{14}:NOH$ is formed and this is derived from the pinene of the turpentine and melts at 131°-132°C., whereas nitroso-limonene or carvoxime from limonene, one of the normal constituents of oil of orange peel, melts at 72°.

The formation of nitrosates:—

If a terpene is treated with amyl nitrite in the presence of nitric acid, the oxide of nitrogen N_2O_4 or $NO \cdot ONO_2$ is first produced:—

and then reacts with the terpene to give a nitrosate:—

In general, the nitrosates are more soluble than the nitroso chlorides and often will not crystallise, but they have been found useful in the separation of definite compounds. For example, it has been found that the unsaturated salts of the terpenes with two ethylene linkages yield nitroso chlorides or especially nitrosates as readily as the corresponding hydrocarbons, so that the liquid limonene and dipentene hydrochlorides, can be readily precipitated by the addition of an alkyl nitrite and hydrochloric acid or nitric acid so as to form crystalline insoluble nitroso chlorides or nitrosates according as the formula is one of the following:—

These are called respectively hydro-chloro-nitroso-chlorides and hydro-chloro-nitrosates; these compounds are very interesting in that they crystallise with the greatest ease, but, unfortunately, are not stable and decompose on attempting to melt them.

Another reaction of the greatest importance in connection with the terpenes, is the formation of nitrolamines when nitroso chlorides, nitrosites, nitrosates, etc., enter into combination with certain organic amino compounds or bases:—

Forming a nitrolamine hydrochloride.

Nitrolamines may be prepared from such terpenes as pinene, limonene, sylvestrene and terpinene. They are characterised by the fact that they crystallise well, are stable, and possess definite melting points. Using pinene as an example, it can be shown that these nitrolamines may be very important factors in the identification of terpenes. The pinene nitrolamines are produced by the action of primary or secondary bases on pinene nitroso-chloride:—

and by using an excess of the base or some other simple means, the hydrochloric acid is removed, giving rise to the free nitrolamines; the chief bases used are benzylamine $C_6H_5 \cdot CH_2 \cdot NH_2$ and piperidine $C_5H_{10} \cdot NH$. The following table of the pinene nitrolamines will explain itself:—

Table of pinene nitrolamines and their melting points.

Pinene nitrol ammonia ..	123°-125°C
" " piperidide ..	118°-119°C
" " propylamine ..	96°C
" " amylamine ..	105°-106°C
" " allylamine ..	94°C
" " benzylamine ..	122°-123°C

After this brief introduction to the terpenes, the individual members and their more important derivatives may be tabulated:—

Aliphatic terpenes.

This homiterpene is a liquid boiling at 33.5° and has a specific gravity of 0.699, and gives with hypochlorous acid a characteristic dichlorhydrin $\text{C}_5\text{H}_{10}\text{O}_2\text{Cl}_2$, melting at 80°-81° and a dibromhydrin melting at 86°. It does not form crystalline additive compounds.

Myrcene :—

This substance belongs to the open chain olefinic terpenes, and, like ocimene, is not a true terpene. Myrcene was isolated by Power and Kleber from oil of bay leaves and sassafras leaf oil; it is a liquid which boils under atmospheric pressure at about 167°, but at the same time polymerises; under 20 mm. pressure it boils at 67°-68°, the specific gravity is 0.802 and the refractive index is 1.4673; this is very low and indicates that it contains three double linkages. The hydrocarbon does not form crystalline addition compounds, but on oxidation is readily converted into succinic acid, melting at 184°-185°.

When myrcene is heated to 40°C with glacial acetic acid and dilute sulphuric acid there is produced an alcohol myrcenol $\text{C}_{10}\text{H}_{16}\text{OH}$, this is a liquid having an odour of lavender and yielding a crystalline phenyl urethane melting at 68°, and although myrcenol is isomeric with linalol, this urethane distinguishes between the two. It has already been stated that a β myrcene has been prepared synthetically by Ostromisslensky and Koschelev.

Ocimene :—

This substance was discovered by van Romburgh in 1901, in the leaves of ocimum basilicum. It is a liquid boiling at 172°,

has a specific gravity of 0.801-0.803, and a refractive index of 1.4857. Enklaar discovered that when ocimene was heated it was converted into an isomer, allo-ocimene boiling at 188°. This allo-ocimene is considered to have the formula:—

Aliphatic terpene alcohols.

Geraniol :—

This alcohol is of the utmost importance and is isolated on a large scale from either palmarosa or citronella oils, it occurs very widely distributed in essential oils such as citronella, lemon grass and the principal geranium oils, which are derived from the fresh herbs of various species of pelargonium, such as the varieties cultivated in France, Spain, Algeria, and Corsica. It occurs, associated with citronellol, in the rose oils and in smaller amounts in the oils of ylang ylang, lavender, neroli, petitgrain, spike, sassafras and linaloe. In addition to occurring as the free alcohol, it is also found as the esters of acetic and tiglic acid; further the geranium oils contain considerable quantities of the free alcohol, together with geraniol acetate and small quantities of the esters of acetic, caproic, butyric, and valerianic acids.

In order to isolate geraniol from the oils which contain it in sufficient quantity, it is first necessary to boil the oil with alcoholic potash or the like to bring about the hydrolysis of the esters, after which the residual oil is carefully fractionated, *in vacuo*. In this way a fraction rich in geraniol is obtained and after drying is ground with anhydrous calcium chloride with which the geraniol forms a solid mass. The mass is well washed with petroleum ether or benzene and then rapidly filtered so as to avoid contact with air or moisture, and finally this calcium chloride compound of geraniol is decomposed into its constituents by mixing with water. The geraniol separates as an oil which is distilled and collected between 228°-230°. To obtain a pure geraniol of fine aroma is an exceedingly difficult operation, and much skill and knowledge is necessary in order to obtain a first-class product. Pure geraniol is a liquid having

a sweet rose-like odour; at 760 mm. the boiling point is 229°-230°, at 18 mm. it is 121° and at 10 mm. is 110°-111°; the specific gravity at 15° is 0.883 to 0.886, and the refractive index at 20° is 1.4766 to 1.4786.

Nerol is a stereo chemical isomeride of geraniol (*v.s.*)

This alcohol is an exceedingly difficult one to isolate, and it occurs chiefly in otto of rose and neroli oil. The oils which contain it also contain much geraniol and this is first removed with calcium chloride and from the residual oil the nerol can be isolated by preparing the phenyl urethane or the allophanate. Pure nerol has a boiling point of 115°-117° at 17 mm., the specific gravity is 0.881 at 15° and the refractive index is 1.47539 at 15°. This alcohol has a very sweet and penetrating odour and the commercial article boils at 226°-227° under 17 mm.

Linalol—

This important alcohol is isomeric with geraniol, but is of quite different constitution. It is found very widely distributed in nature and is the principal constituent of linaloe oil in which it occurs in the free state, it is also found in considerable quantities as linalyl acetate in bergamot, and lavender oils and in various forms in the oils of petitgrain, neroli, ylang ylang, cananga, limes, sago, spike, thyme, lemon, origanum, sassafras leaf, Russian spearmint and basil. From oils rich in linalol and its esters, the linalol is separated by fractionation preceded by saponification, but it is rather doubtful whether pure linalol has ever been obtained. It is an optically active alcohol and whilst both varieties occur in essential oils the laevo variety is the more usual. In 1914, Paolini and Divizia, prepared a pure linalol by conversion into linalyl hydrogen phthalate and crystallisation of the strychnine salt, followed by treatment with alkali. Linalol is a rather unstable alcohol, having a boiling point 197°-199°; under 10 mm. it boils at 85° to 87°; the specific gravity varies from 0.870 to 0.875, the optical rotation is variable according to the source and purity of the alcohol, but the limits—20° 7' to + 19° 18' are representative, the refractive index varies from 1.4630-1.4690. This alcohol

can be identified by means of its phenyl urethane melting point 65°-66° or the naphthyl urethane melting at 53°.

Citronellol—

This alcohol is found in dextro and laevo rotatory forms in the rose geranium oils, whilst otto of rose itself contains the laevo form; it also occurs associated with the corresponding aldehyde in citronella oil. This alcohol very closely resembles rhodinol, indeed it is also known as rhodinol, reuniol, and roseol; actually, however, true rhodinol has the constitution

and is a liquid with a pleasant rose-like odour, its acetate boils at 115° under 10 mm., the butyrate at 142°-143° under 13 mm., the isobutyrate at 135°-137° under 13 mm., and the benzoate at 194°-195° under 12 mm. Pure citronellol was obtained by Wallach from its admixture with geraniol, by heating the two alcohols with water under pressure at 250°, when the geraniol was changed into hydrocarbons. It can also be obtained by the help of phthalic anhydride, as the citronellol acid phthalic ester is an oil. Citronellol boils at 225°-226°, has a specific gravity of 0.860 to 0.862, its rotation varies from 4° 20' to + 4°, and its refractive index is between 1.4586 and 1.4589. It can be identified by its silver phthalate which melts at 125°-126°.

Aliphatic terpenes aldehydes and ketones.

Citral or geranial—

This aldehyde is found in the oils of Backhousia citriodora, balm, bay, cedrat, lemon, lemongrass, limes, orange, pimento and verbenia. It results when geraniol or linalol is oxidised with chromic acid, and it can be obtained in other ways. This substance exists in two isomeric forms corresponding to the alcohols nerol and geraniol. It can be isolated from essential oils by treating them with sodium bisulphite, with which it forms a soluble crystalline compound, which can be isolated and which

on treatment with sodium carbonate, liberates the free citral. Citral is a yellow oil having a boiling point of 228° – 229° at 760, of 117° – 119° at 20 mm., of 110° – 112° at 12 mm., the specific gravity is 0.890–0.897, the refractive index is 1.4891–1.493. It can be identified by its semi-carbazone melting at 164° in the case of α citral or at 171° for the semicarbazone of β citral. Citral is very easily decomposed; for example, by the action of acids and caustic alkalis it becomes cymene whilst boiling with potassium carbonate decomposes into acetaldehyde and methyl heptanone, this latter also occurs in lemongrass oil. It is important to remember that citral also combines with a weak solution of sodium sulphite in the presence of sodium bicarbonate, whilst citronellal only combines with concentrated solutions and methyl heptanone does not combine at all in alkaline solutions, and these facts afford a method by which citral can be separated from citronellal and methyl heptanone. Neral, is considered to be β citral and is obtained by the oxidation of nerol, it has a specific gravity of 0.8888 and its refractive index is 1.49001. Citral is exceedingly important as the flavouring substance of the oil occurring in the rind of lemons and further as the raw material for the manufacture of ionone or artificial violet oil.

Citronellal—

This substance is found to the extent of 95 per cent. in the oil of eucalyptus citriodora and also in the citronella oils, it is a liquid having a boiling point of 205° – 208° , or at 25 mm. 103° – 105° , the specific gravity is from 0.855–0.860 and the refractive index from 1.444–1.4481, its optical rotation is usually dextro from $+8^{\circ}$ to $+12^{\circ}$ and that derived from Java citronella oil is laevo rotatory. This aldehyde is extremely sensitive to acids and alkalis; with acids isopulegol is formed and finally cymene, whilst caustic soda converts it into a resin: it can be identified by means of its semicarbazone which melts at 84° . Methyl heptanone

This occurs in the oils of lemon, lemongrass, citronella, linaloe and palmarosa.

It is a liquid having an odour of amyl acetate, boils at 170° – 174° , has a specific gravity of 0.850–0.855 and a refractive index of 1.438–1.440. It gives a semicarbazone melting at 136° – 138° , but its oxime is a liquid boiling at 115° at 15 mm. and, though it forms a bisulphite compound, the original ketone cannot be regenerated from this.

Aliphatic sesquiterpene.

An olefinic sesquiterpene called sesquictronellene $\text{C}_{15}\text{H}_{24}$, has been isolated from Java citronella oil; it boils at 270° – 280° , has a specific gravity of 0.849, a refractive index of 1.5325, and is slightly dextro rotatory.

Aliphatic sesquiterpene alcohol.

Farnesol $\text{C}_{15}\text{H}_{25}\cdot\text{OH}$. This alcohol was discovered in 1904 in otto of rose, and also in acacia oils, musk seed oil and lime blossom oil. It is a liquid having an exceedingly pleasant odour, and boiling at 160° under 10 mm., whilst the specific gravity is 0.894, and the refractive index 1.488; solid derivatives of this alcohol have not been obtained.

Aliphatic sesquiterpene ketone.

Dorenone. $\text{C}_{15}\text{H}_{26}\text{O}$.

This was discovered in 1917, and isolated from oil of gum ammoniacum; it is a liquid boiling at 145° – 155° under 12 mm., it has a specific gravity of 0.8765, and a refractive index of 1.4716; the rotation is $+3^{\circ}30'$ and its oxime melts at 88° , whilst its semicarbazone melts at 124° .

The bicyclic terpenes.

Pinene. $\text{C}_{10}\text{H}_{16}$ or

This hydrocarbon occurs in both dextro and laevo rotatory forms, and is very widely distributed as a constituent of essential oils. It forms the chief constituent of the turpentine oils, and is found in such essential oils as pine, eucalyptus, camphor, coriander, fennel, juniper, rosemary, mace, lemon,

spike, thyme, etc. There are several isomeric forms, of which the α and β varieties, are well known; actually α pinene is the ordinary variety; a chemically pure pinene can be obtained from pinene nitrosochloride. This boils at 155° — 156° , has a specific gravity of 0.858 at 20° , and a refractive index of 1.4655; this is considered to be the α variety. The dextro pinene has been isolated from Grecian turpentine and has an optical rotation of $+48^{\circ}$.

β pinene, also known as nopinene, occurs in the oils of hyssop, and pinus sibirica.

Firpene $C_{10}H_{16}$ isolated from the turpentine of the Western fir, closely resembles pinene. It boils at 152° — 153° , has a specific gravity of 0.8598, and a rotation of -47° , whilst its refractive index is 1.47299.

TABLE OF THE PINENE GROUP.

	B.P.	Sp. Gr.	n.
α pinene ..	155° — 156°	0.858	1.4655
β pinene ..	162° — 163°	0.866	1.7224
Firpene ..	153° — 154°	0.860	1.4730

Derivatives of pinene, etc.:

A crystalline dibromide melts at 169° — 170° , a mono-hydrochloride melts at 125° and boils at 207° — 208° . The nitroso chloride melts usually at 103° , but this can be raised to 115° , and nitrosopinene melts at 130° — 131° . The foregoing are from α pinene.

Camphene :—

This is a solid terpene, and there are apparently a number of very closely related varieties. The dextre variety occurs in camphor, ginger and spike oils, the laevo variety is found in citronella, valerian and certain pine oils, the so called natural camphene is found in Siberian pine needle oil, and citronella oil. It is a crystalline solid, having as a usual melting point 49° — 50° , though it can be raised to 54° . It boils at 160° — 161° , and has a specific gravity of 0.850 at 48° . Of its derivatives, the dibromide melts at 90° , the hydrochloride melts at 150° — 152° , and it does not give a nitrosochloride.

Fenchene. $C_{10}H_{16}$.

This hydrocarbon does not occur in

essential oils, and will, therefore, not be described.

Santene.

This terpene has been found in sandalwood oil, and in Siberian turpentine oil. It is sometimes called norcamphene, and is a liquid boiling at 140° ; the specific gravity is 0.863—0.870, and the refractive index 1.466—1.470.

Sabinene.

This was originally isolated from savin oil, and has also been found in cardamom oil and marjoram oil. It is a liquid boiling at 162° — 170° , with a specific gravity of 0.840, the refractive index is 1.466 and the substance is optically active.

Monocyclic terpenes or menthadienes.

Limonene and dipentene :—

It appears probable that dipentene is the racemic form of limonene, though more proof of this statement is still required. Limonene is found in large quantities in the oils of lemon, orange, dill, caraway and bergamot as the dextro variety, whilst Russian peppermint, American spearmint and the pine oil from *Abies alba* contain the laevo variety. Limonene boils at 175° — 176° and has a specific gravity of 0.846—0.850 and a refractive index 1.474—1.475, whilst the rotatory power is -105° to $+106^{\circ}$. Limonene contains two ethylene linkages and forms a

tetra bromide melting at 104° - 105° . The nitroso chloride occurs in four different forms, two, the α and β , from dextro limonene and two from laevo limonene. Dipentene is found in Swedish and Russian turpentine and also in the oils of bergamot, camphor, cubeb, fennel, thyme and nutmeg, it is also a product of the destructive distillation of various resins, it boils at 178° , has a specific gravity of 0.845 and a refractive index of 1.4720-1.4730. Its chemistry has been fully elucidated by W. H. Perkin, who succeeded in making it synthetically and at the same time accomplished the synthesis of terpineol. The dipentene tetra-bromide is less soluble in ether than is limonene tetra-bromide and it melts at 126° , whilst the nitrosochloride occurs in two forms.

Terpinolene :—

Results from the isomeric changes of other terpenes under the influence of sulphuric acid and also occurs naturally in oils of elemi and coriander. It is a liquid boiling at 185° - 190° .

Terpinene :—

This terpene was discovered in oil of cardamoms and three isomeric forms are known. The α terpinene is a constituent of the oils of cardamoms, coriander and elemi. The β variety has not been found in essential oils, whilst the γ form is contained in the oils of ajowan, coriander, lemon and yellow pine. When certain terpenes undergo isomeric change they yield terpinene, which is a mixture of the α and γ varieties, and is optically inactive, boils at 180° , has a gravity of 0.842 and forms a nitrosite melting at 155° .

Phellandrene :—

The dextro form of this is found in the oils of elemi, bitter-fennel, and water-fennel whilst the laevo form is in certain eucalyptus and pine needle oils. In 1886, Pesci discovered a variety of phellandrene in water fennel oil which has been called the β form. α phellandrene is a liquid boiling and an optical rotation of $+40^{\circ}$ to -84° , at 173° - 175° has a specific gravity of 0.848 this α variety gives two nitrites, which are probably cis and trans configurations, one melts at 113° and the other at 105° .

The β phellandrene has a specific gravity of 0.850 to 0.854 and a rotation $+14^{\circ}$, it also yields two nitrites, one melting at 102° and the other at 98° .

Terpenes of the meta series :—

Sylvestrene.

This is a dextro rotatory terpene found in Swedish pine oil, Russian turpentine and in certain pine needle oils. The liquid boils at 176° - 177° and has a specific gravity of 0.850 and a rotation of $+66^{\circ}$. It gives an interesting reaction when a drop of strong sulphuric acid is added to a solution of the sylvestrene in acetic anhydride, the result being a deep blue colouration. The same reaction is given by carvestrene, and both of these terpenes are derivatives of metacymene and have been prepared synthetically by W. H. Perkin, carvestrene in 1907 and sylvestrene in 1910.

Terpene alcohols and ethers.

Terpineol :— $C_{10}H_{17}OH$

This alcohol occurs in several isomeric forms, d-terpineol has been found in the oils of cardamoms, lavender, marjoram

spike, etc., whilst an inactive form is known to occur in cajuput oil. The chemical constitution of terpineol admits of there being four isomeric forms, and three of these are well known. The liquid terpineol of commerce obtained from terpin hydrate by the action of dilute sulphuric acid, is a fairly thick liquid, having a lilac odour, its specific gravity is from 0.935 to 0.945, and the boiling point varies from 210° to 220°. The pure α terpineol is optically inactive, melts at 35° and boils at 217°, the β terpineol melts at 32°, whilst the γ melts at 69°-70°. Much care is required in the manufacture of the liquid terpineol of commerce to insure its freedom from terpenes, which considerably modify its odour and affect its solubility.

Borneol :—

When camphor is reduced there is formed the secondary alcohol borneol :—

The dextro form is found as Borneo camphor in *Dryobalanops camphora*, whilst the laevo form is the camphor from *Blumea balsamifera*. The dextro form of borneol is also found in the oils of rosemary and spike lavender, whilst the laevo form is found in the oils of citronella, feverfew and valerian. There is also an isoborneol obtained by treating camphene with a mixture of sulphuric and acetic acids followed by saponification, it is a crystalline substance melting at 212°. Borneol melts at 203°-204°, and its specific rotation varies from -37° to $+37^\circ$. It will be convenient to deal with the medicinal value of borneol compounds at this point.

Of the borneol containing oils, some of the most interesting are the pine oils, many species of which are characterised by containing varying quantities of bornyl esters, usually in the form of bornyl acetate. This acetate, found in various pine oils, occurs to the extent of 30 or 40 per cent. in oil of *pinus sibirica*, it has a most refreshing and fragrant odour, being an absolute necessity for the reproduction of pine odours. It is prepared artificially by the action of acetic anhydride on borneol, or by the treatment of borneol with glacial

acetic acid in the presence of a small quantity of a mineral acid; when quite pure and crystallised from petroleum ether, it forms rhombic hemihedric crystals melting at 29°, and is either dextro or laevo 40° according to the alcohol from which has been prepared. It has a specific gravity of 0.991, a refractive index of 1.465 to 1.4665, and boils at 98° under 10 mm. pressure, and is soluble in three volumes of 70 per cent. alcohol. The commercial article is usually a mixture of dextro and laevo varieties, and is frequently liquid, and it remains in a state of superfusion when it has once been melted; it should contain at least 98 per cent. of the ester and the gravity should be between 0.988 and 0.992.

It is well known that the oil of *pinus sylvestris* was official in the Pharmacopoeia of 1885, but in 1895, Umney showed that such oils as were in commerce under that name were actually from other species, more especially from *Abies excelsa*. In 1898, the oil of *Pinus pumilio* took its place in the B.P. This is an oil with an extremely pleasant odour, and containing varying proportions of bornyl acetate, usually about 4 per cent. It was suggested that this again should be replaced by the most fragrant of the pine series, such as *pinus sibirica*. At one time this oil was distilled in very large quantities in northern Russia and on the slopes of the Ural mountains.

In the class of oils containing borneol and its esters, the most important member is rosemary oil, though but little of this oil is now produced in England. The principal countries producing rosemary oils are France, Spain and North America, and at one time Dalmatia, though this almost ceased to appear on the market before the war. The English oil is characterised by a fineness of bouquet which is certainly not equalled by any of the others. These oils may be dextro or laevo rotatory, and the proportion of borneol or of alcohols calculated as borneol in rosemary oils, varies very considerably, some of the finest containing as low as 8 per cent. of borneol, whilst in others there is as much as 22 per cent., and the bornyl acetate is between 4 and 6 per cent.

Much attention has been given to the use of the esters of borneol and menthol for medicinal purposes, and the medical profession has for many years appreciated

the value of valerian for the treatment of nervous ailments, but it is only in recent years that it has been recognised that the root owes its chief physiological activity to the essential oil contained in it, and that its therapeutic value is due to bornyl-iso-valerianate,

Under the name of "Bornylval" this substance was introduced into medicine, and its value is very considerable as an anti-spasmodic and sedative and as a general tonic for the nervous system. This substance may be regarded as the natural active constituent of valerian root; it is prepared artificially by the action of iso-valeric acid on borneol. It is a limpid liquid of a rather pleasant aromatic odour, slightly reminiscent of valerian; it boils at 255° – 260° , and has a specific gravity at 20°C . of 0.0951–0.956. This ester is like terpineol acetate rather resistant to saponification and requires an excess of alkali and at least two hours boiling to complete the reaction. Average good qualities correspond to the following characters:—specific gravity, 0.953–0.956; optical rotation about -35° , refractive index, 1.4620–1.4635, and the boiling point is 128° – 130° at 10 mm.

Gynoval, valisan and such like bodies have been used in medicine; gynoval is the iso-valerianic ester of iso-borneol,

It is a colourless neutral liquid with a peculiar aromatic odour and a slightly oily taste. It boils at 132° – 137° under 12 mm. and has a specific gravity of 0.952–0.957. The preparation is very sparingly soluble in water, but it dissolves readily in alcohol or ether. The pharmacological investigation of this substance shows it to possess the typical action of valerian, whilst its toxicity is but slight.

The bromo-iso-valerianic ester of borneol was introduced under the name of "Valisan,"

It is a liquid having a slight odour and a mild taste, and is insoluble in water, but dissolves easily in organic solvent; at one time it was called "Eubornyl," and is stated to be a useful sedative for the treatment of headache and insomnia.

These substances were nearly all of foreign origin, and have been introduced to show the utility of some of the constituents of essential oils, and several other esters of borneol, such as the formate, occur in

essential oils, whilst bornyl butyrate, a liquid boiling at 120° – 121° under 10 mm., and having a specific gravity of 0.966 and a refractive index of 1.4638 and a rotation of $+22$, together with the propionate, a liquid having a boiling point of 109° to 110° and a specific gravity of 0.979, and a rotation about $+25^\circ$ with a refractive index, are in commerce.

Menthol:—

This is a crystalline alcohol which separates on cooling oil of peppermint. When pure, it melts at 44° , but usually the commercial melts slightly lower, between 43° and 43.5° , and certainly not below 42.5° . The boiling point is 217° , if care be taken to have the stem of the thermometer entirely immersed in the vapour, otherwise it will record about 212° . Its specific rotation is about -50° in alcoholic solution, and only the laevo variety is found in nature.

The esters of menthol have also had wide application and menthyl acetate and valerianate occur in peppermint oil. The menthyl acetate is easily obtained by the acetylation of menthol and is a liquid boiling at 228° , the specific gravity is 0.925 to 0.930. the specific rotation is -72° to $+79^\circ$, and the refractive index is 1.446–1.447. Menthol valerianate found in American peppermint oil has a refreshing odour, which is not distinctive either of menthol or of valerianic acid. At one time a mixture of menthol valerianate and free menthol was in commerce under the name of "Validol," this was a colourless viscous liquid with a pleasant odour and often contained up to 30 per cent. of free menthol, and was recommended to be taken on sugar as a preventive of sea sickness. There was also a liquid camphorated validol containing 10 per cent. of camphor and 90 per cent. of the validol, this was offered as a local anæsthetic for toothache. Another ester was the menthol ethyl glycolate:—

introduced under the name "Coryfin," it was a colourless liquid with a barely

perceptible odour of menthol, and was intended to be used as a cure for nasal catarrh of the nose and throat and to be rubbed on the forehead to produce a refreshing cooling feeling, which would persist a long time and alleviate nervous headache. Another substance, menthol borate:—

was introduced under the name of "Estoral." It was obtained by the action of boron trichloride on menthol and was a white crystalline powder intended to be made into a snuff for catarrh of the nose. It was a fairly stable substance, insoluble in water and alcohol, but in contact with moisture and mucous membranes it broke up fairly rapidly into its components boric acid and menthol. The salicylic ester of menthol has been made and forms a colourless liquid insoluble in water and boiling at 189° under 11 mm.

Sabinol:—

This alcohol was discovered by Fromm (1898) in savin oil, in which it occurs as an acetate and as the free alcohol, it is a slightly odorous liquid boiling at 210° to 213° , and has a specific gravity of 0.943-0.950 and a refractive index of 1.488. There is also known a pure dextro sabinol boiling at 208° and having a specific gravity of 0.9518 and a refractive index of 1.4895, whilst the rotation is $+76^\circ$.

Fenchyl alcohol:— $\text{C}_{10}\text{H}_{17}\text{OH}$

It is obtained from the yellow pine oil which resulted from the steam distillation of old stumps of *Pinus palustris*, it is crystalline, melts at 45° and boils at 202° - 203° .

Thujyl alcohol:— $\text{C}_{10}\text{H}_{17}\text{OH}$.

Is isolated from oil of wormwood and can also be produced by the reduction of thujone, it is a liquid boiling at 210° - 212° , with a specific gravity of 0.927.

Monocyclic terpene ketones.

Carvone:— $\text{C}_{10}\text{H}_{14}\text{O}$ or

The dextro variety occurs in caraway and dill oils, whilst the laevo form is found in the oils of kuromoji and spearmint. It is a ketone with two double bonds and is a derivative of di-hydro cymene. Its oximes are identical with the nitroso limonenes. Pure carvone boils at 230° - 231° and has a specific gravity of 0.963 to 0.966 and a rotation of -59° , whilst the refractive index is 1.497-1.500. Carvone forms an additive compound with sulphuretted hydrogen, which crystallises well and from this compound it can be regenerated and this forms a means of preparing pure carvone.

Pulegone:— $\text{C}_{10}\text{H}_{16}\text{O}$ or

This is the chief constituent of the oils of pulegium (European pennyroyal) and hedeoma (American pennyroyal), it is a liquid boiling at 223° - 224° , has a specific gravity of 0.929-0.936, a rotation of $+20^\circ$ to 25° , and a refractive index of 1.470. It forms the usual compounds that distinguish ketones, whilst the iso-pulegone differs in physical properties and does not combine with sodium bisulphite.

Menthone:— $\text{C}_{10}\text{H}_{18}\text{O}$ or

This substance is a saturated ketone found, together with menthol, in peppermint and hedeoma oils.

It is a liquid easily made by the oxidation of menthol, it boils at 207° , has a specific gravity of 0.896, a specific rotation of -29° and a refractive index of 1.449. Although this ketone yields the usual derivatives, it does not combine with sodium bisulphite.

Bicyclic terpene ketones.

Camphor :— $C_{10}H_{16}O$ or

This substance occurs in the camphor tree, as a dextro rotatory form and other essential oils contain traces of it, the laevo variety has been found in the oil of *Matricaria parthenium*. It is a colourless, crystalline substance, melting at 175° and boiling at 204° . It has been made artificially on a commercial scale, starting with the raw material, turpentine; the synthetic product is optically inactive and is stated to be deficient in physiological properties. Camphor is not of great importance as a perfume substance, but enormous quantities are used in the manufacture of celluloid. There is a homologue of camphor called "Matico camphor," which is isolated from the oil of Matico leaves; it is crystalline and melts at 94° .

Fenchone :— $C_{10}H_{16}O$ or

This substance was discovered in 1890, the dextro form occurs in oil of fennel and the laevo in thuja oil, it is an oil having a camphor-like odour and boils at 103° , when cooled it solidifies and then melts at about $5^{\circ}C$, the liquid product has a specific gravity of 0.946-0.948 and the rotation is -72° . It appears not to react either with sodium bisulphite or phenylhydrazine, though it does yield an oxime and a semicarbazone. Fenchone distilled with phosphorus pentoxide yields metacymene.

Thujone :— $C_{10}H_{16}O$ or

This is also known as tanacetone and salvone, and occurs in two modifications. The α form is the laevo variety, and is obtained from thuja oils, and boils at 170° . β thujone is the dextro variety and occurs as a constituent of the oils of sage, tansy and wormwood. Actually, both forms can be isolated from the oils of wormwood and sage. This ketone is a colourless liquid boiling at 201° , has a specific gravity of 0.912—0.917 and a refractive index of 1.450—1.451.

Umbellulone :— $C_{10}H_{14}O$ or

Power and Lees discovered this bicyclic ketone in Californian laurel oil; it is a liquid boiling at about $98^{\circ}C$ under 10 mm., and has a specific gravity of 0.958 and a refractive index of 1.4895, and is laevo rotatory.

Monocyclic sesquiterpenes.

Limene :— $C_{15}H_{24}$.

This substance was discovered by Burgess and Page in the oils of lime and of lemon, and is the same substance isolated from

oil of bisabol myrrh formerly called "bisabolene." It is a liquid boiling at 262° , and resinifies very easily.

Zingiberene :— $C_{15}H_{24}$ or

It is isolated from oil of ginger, boils about 270° and is optically active. Much work has been done recently on this terpene. The alcohol zingiberol is also in ginger oil together with zingerone.

Bicyclic sesquiterpenes

Cadinene :— $C_{15}H_{24}$.

This occurs as a constituent of the oils of cade, cubebs, camphor, cedar wood, galbanum, juniper, patchouli and savin. It is a liquid boiling at 272° — 274° , has a specific gravity of 0.921 and a refractive index of 1.5064, and is *laevo* rotatory. It easily oxidises, and resinifies on exposure to the air. Oil, in which these changes have commenced, gives a remarkable reaction; when dissolved in glacial acetic acid or chloroform and shaken with a few drops of strong sulphuric acid, a green colour develops gradually changing to blue, and with a slight warming the mixture becomes red.

Caryophyllene :— $C_{15}H_{24}$.

Is contained in oils of clove and copaiba. It is a liquid boiling at 258° — 260° , and has a specific gravity of 0.908 and a refractive index of 1.5009. When boiled with glacial acetic acid and sulphuric acid caryophyllene yields an alcohol which melts at 96° and boils at about 288° , and from this, by the elimination of a molecule of water, there results the isomeric sesquiterpene "Clovone," which boils at 262° and has a gravity of 0.930, but this cannot be converted into a crystalline alcohol.

Humulene :— $C_{15}H_{24}$.

Is found in oil of hops and is not yet fully investigated, but appears to be a mixture of caryophyllenes.

Santalene :— $C_{15}H_{24}$.

Occurs in two forms in sandalwood oil; the alpha variety boils at 252° — 253° , and the beta variety at 261° — 262° .

Selinene :— $C_{15}H_{24}$.

Is found in oil of celery, is dextro rotatory $+35^{\circ}$, and boils about 270° , at 120° under 16 mm., the specific gravity is 0.9197 and the refractive index 1.4986.

Aromadendrene :— $C_{15}H_{24}$.

Appears to occur mainly in the eucalyptus oils, and in a liquid boiling about 263° .

Tricyclic sesquiterpene :—

Cedrene :— $C_{15}H_{24}$.

This is found in oil of cedar wood and is a liquid boiling at 262° — 263° , and has a specific gravity of 0.936, and is *laevo* rotatory.

Bicyclic sesquiterpene alcohols.

Santalol :— $C_{15}H_{24}O$.

There are two forms of this alcohol, and they form together about 90 per cent. of sandalwood oil. The alpha compound is a liquid boiling at 300° — 301° , the specific gravity is 0.985, and the rotation slightly dextro. The beta variety is stated to boil at 309° — 310° , has a specific gravity of 0.986, and is *laevo* rotatory. In former days a salicylic acid ester of sandalwood oil called "Santyl," was in commerce as a colourless liquid offered for treatment of venereal disease, and a so-called methyl ester of santalol under the name of "Thyresol," in the form of a colourless liquid, boiling at 149° — 156° under 16 mm, and having a gravity of 0.930, was introduced. There was also a neutral camphoric acid ester of santalol under the name of "Camphosal," $C_8H_{14}(COOC_{15}H_{23})_2$; it was a yellow oil having a bitter taste, and a feeble aromatic smell, and a specific gravity of 0.987.

Eudesmol :—

This is a solid alcohol found in eucalyptus oil, and melts at about 79° .

Tricyclic sesquiterpene alcohols.

Cedrol or cedar camphor :— $C_{15}H_{26}O$.

Is found in cedar wood and cypress oils as a crystalline compound melting at 87° , and boiling at about 293° .

Cubeb camphor :— $C_{15}H_{26}O$.

Can be obtained from oil of cubebs and melts at $70^{\circ}C$, and boils at 248° . Patchouli oil deposits a crystalline alcohol $C_{15}H_{26}O$ called a "camphor," which melts at 56° .

OBITUARY.

SIR WILLIAM STEVENSON MEYER, G.C.I.E., K.C.S.I., B.A.—Sir William Meyer, High Commissioner for India, and formerly Indian Finance Minister, died suddenly in London on October 19th. Son of the late Rev. Theodore J. Meyer, he was born on February 13th, 1860, and, at the age of nineteen, on completing his education at University College, London, gained entrance by competition to the Indian Covenanted Civil Service, in which he had a very distinguished career of nearly forty years' duration. After filling, with credit, numerous responsible posts in the Southern Presidency, he was called in 1898 to the seat of the Supreme Government to be Deputy Secretary in the Finance Department. Three years later he reverted to duty in Madras, and subsequently for about eighteen months was Editor of the monumental *Imperial Gazetteer of India*. Recalled to imperial headquarters, he was Financial Secretary to the Government of India from 1905 to 1909, when he was appointed Chief Secretary to the Government of Madras. He was a member of the Decentralisation Committee (1907-9), a delegate to the International Opium Commission at the Hague (1911-12), and a member of Lord Nicholson's Committee on Indian army administration (1912-13). He became Financial Member of Lord Hardinge's Council in June, 1913, as successor to Sir Guy Flectwood Wilson. Sir William Meyer's term of office as Finance Minister was marked by unparalleled difficulties and he was subjected to some criticism, particularly in connexion with what the public commission presided over by Lord George Hamilton called the "lack of provision made for the wants of the Mesopotamia Expedition during the first sixteen months of its operations." Sir W. Meyer, however, claimed, as the then Secretary of State for India, Mr. Austen Chamberlain was authorised to tell the House of Commons, that nothing put forward as a military necessity had been refused. Moreover, the Commission recognised that no evidence had been produced to show that any urgent demand made by the military authorities was definitely rejected by the Finance Department. Sir W. Meyer retired in 1918, and after his return to England took an active part in the organisation of Earl Haig's splendid movement on behalf of ex-officers and soldiers. In 1920 he was selected to be the first High Commissioner for India, and as doubtless such a strenuous worker would have desired, has died in harness.

He joined the Royal Society of Arts in 1901 and was a valuable member of the Indian Section Committee. The able paper he contributed to the Society in 1920 on "The Indian Currency System and its Developments" was described by one of the experts who spoke on

the occasion as a classic on the subject and likely to be of great historical importance. More recently Sir William occupied the chair when Mr. Alexander Howard's paper on "The Timbers of India and Burma" was read.

He translated into English M. Chailley's "L'Inde Britannique," also revising the French text.

GENERAL NOTES.

VICTORIA AND ALBERT MUSEUM.—A number of interesting pieces of English furniture recently presented by Mr. Douglas Eyre have been placed on exhibition in Room 56 of the Woodwork Galleries of the Museum. These pieces of furniture date from the latter part of the 17th century to the middle of the 18th century; they have been handed down in the donor's family and thus have an important documentary interest. They include a winged armchair of about the year 1700 embroidered in coloured wools with David playing the harp before Saul, and other Biblical and mythological subjects; and a large double-back settee with three chairs and a stool of the time of James II. Among examples of the 18th century, the most valuable is a set of mahogany chairs, richly carved with ornament of the middle of the century and the crest of the Eyre family. This gift is of great importance in strengthening the English furniture in the Museum at a time when high prices and lack of money make it difficult for a Government institution to compete with wealthy collectors.

ARTIFICIAL SILK IN ITALY.—The Italian artificial silk industry, says an American Consular report, has attained a considerable development both as regards capital invested, labour employed, raw material and actual production. The industry is a comparatively new one, being known in the world's markets for only 30 years and in Italy for about 15. It produces by means of four diverse systems a fibre from wood pulp, having a certain external likeness to natural silk and considerable affinity to mercerised cotton. The present amount of capital involved is about 420,000,000 lire, and by the end of 1923 it is estimated that the amount will be fully double the above figure. Twelve thousand workmen are now employed and by the close of 1923 it is estimated that the number will be about 20,000. Some of the raw materials used, i.e., soda, carbon bisulphide, sulphuric acid are produced by native industries, and it is hoped that after a time the wood pulp may be also, though at present it is imported principally from Scandinavia. Considerable quantities of cloth, hosiery and knitted goods are being manufactured from the fibre.

VOL. LXX.

FRIDAY, NOVEMBER 3, 1922.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.(2)

NOTICE.

OPENING OF THE 169th SESSION.

The opening meeting of the 169th Session will be held on Wednesday, November 8th, when an address will be delivered by LORD ASKWITH, K.C.B., D.C.L., Chairman of the Council, on "The Value of Strikes and Lock-outs." The Chair will be taken at 8 p.m.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

THE CONSTITUENTS OF ESSENTIAL OILS.

By LIONEL GUY RADCLIFFE, M.Sc.Tech., F.I.C.

LECTURE III.—*Delivered April 3rd, 1922.*

The constituents of essential oils other than those derived from the various classes of terpenes are exceedingly numerous and varied in chemical constitution: it is, therefore, impossible to review the whole of them in this one lecture, and, indeed, those that can be dealt with, will have to be summarised very briefly. The hydrocarbons of the fatty series have already been mentioned, and as these are limited in interest they will not be dealt with further.

Aliphatic Alcohols.

Methyl alcohol :— CH_3OH .

This alcohol frequently occurs in essential oils in the free state associated with diacetyl and furfural and the myristic methyl ester is found in oil of orris, the benzoic methyl ester in oil of ylang ylang, the salicylic ester in the oils of wintergreen and sweet birch and in small quantities in the oil of rue, cassie, cananga, and tuberose, whilst as the methyl ester of anthranilic acid, it is a most important constituent of the oils of neroli and jasmin.

Ethyl alcohol :— $\text{C}_2\text{H}_5\text{OH}$.

This has been found in the aqueous distillates from a few essential oils, especially if the vegetable material has begun to ferment. Its esters occur in many essential oils, e.g., the butyric ester in oil of heracleum, the cinnamic ester in oils of styrax and kaempferia and the caproic ester in oil of cognac.

Normal butyl alcohol :—

Has been found in an ester in chamomile oil, whilst isobutyl alcohol has been isolated from the aqueous distillation of eucalyptus amygdalina.

Iso-amyl alcohol :—

This occurs in the oils of eucalyptus globulus, and Bourbon geranium, and as esters in chamomile and cognac oils; in the eucalyptus oil mentioned above it occurs as an ester of eudesmic acid.

Normal hexyl alcohol :—

Has been found in the oil of male fern and as a butyric ester in the oils of the heracleum species, whilst active hexyl alcohol occurs as an angelic acid ester in chamomile oil. It is a liquid boiling at 157° .

Heptyl alcohol : Oenanthyl alcohol :—

This has been found in oil of cloves, it is a liquid with a very powerful odour, boils at 157° and has a specific gravity of 0.8344, it is manufactured artificially by the reduction of heptyl aldehyde, i.e., oenanthol. The calculated quantity of sodium is melted by heating in dry toluene, the mixture being then vigorously stirred to obtain the sodium in a fine state of division, after which the mixture is cooled in ice with continual stirring, then there is added very slowly a solution of oenanthol in glacial acetic acid and toluene. When reduction is complete water is added to dissolve the sodium acetate, the toluene layer is separated, dried and distilled, giving a 50 per cent. yield of heptyl alcohol.

Octyl alcohol :— $\text{CH}_3 \cdot (\text{CH}_2)_6 \cdot \text{CH}_2\text{OH}$

This has been found in the oil of heracleum as the acetic ester and in oil of pastinac as a propionate, whilst oil of male fern contains it as the isovalerianate. It is a liquid with a pleasant odour and boils at 196° and has a specific gravity of 0.8278.

Ethyl normal amyl carbinol :—

This has been found in Japanese peppermint oil, and when pure boils at 179° , and has a specific gravity of 0.8276 and a refractive index of 1.42755 and is dextro rotatory. It does not form a phenyl urethane with phenyl isocyanate, but with alpha naphthyl isocyanate an alpha naphthyl urethane is obtained crystallising from methyl alcohol, with a melting point of 82° .

Nonyl alcohol :— $\text{CH}_3(\text{CH}_2)_7 \cdot \text{CH}_2\text{OH}$

This is found in sweet orange oil as the caprylic ester, it is extracted from this oil by saponifying the high boiling constituents and extracting the alcohol, which is then purified by converting it into its phthalic acid ester. The alcohol is a liquid with a roselike odour, slightly reminiscent of orange, it boils at 213° under normal pressure and has a specific gravity of 0.840. The isomeric methyl heptyl carbinol has been found in Algerian oil of rue and in clove oil, it is a liquid boiling at 195° – 196° under 760 mm., and has a specific gravity of 0.8273.

Methyl normal nonyl carbinol :—

This secondary undecylic alcohol has been found in the oils of rue and trawas, which latter is a bright yellow oil of unpleasant odour obtained by distilling the leaves of *Litsea odorifera*, a tree found in Java; the alcohol boils at 232° .

Undecylenic alcohol :—

This liquid has been found in oil of trawas leaves, it crystallises on cooling and melts at -12° and boils at 128° under 13 mm.

The aromatic alcohols are of great importance, though comparatively few in number, and of these the following are the best known :—

Benzyl alcohol :— $\text{C}_6\text{H}_5 \cdot \text{CH}_2\text{OH}$.

This occurs naturally both in the free state and in the form of esters in many essential oils, e.g., cassie, gardenia, hyacinth, jasmín, narcissus, tuberose, wallflower and ylang ylang, it is found as the esters benzyl benzoate and benzyl cinnamate in storax

and balsams of Peru and Tolu. It is an oily liquid with a very slight odour, boils at 205° under 760 mm., the specific gravity is 1.050 and the refractive index 1.53804.

Cumic alcohol :—

Has been found together with the corresponding aldehyde in oil of cumin. It is a pleasant smelling liquid, boiling at 246° .

Anisyl alcohol :—

This alcohol has been isolated from Tahiti vanilla, when pure it forms crystals melting at 25° and boils without decomposition at 259° .

Phenyl ethyl alcohol :— $\text{C}_6\text{H}_5 \cdot \text{CH}_2 \cdot \text{CH}_2\text{OH}$.

This alcohol is a natural constituent of neroli and rose oils, and is present in greater proportion in French rose oils than in the Bulgarian ottos; the French ottos, especially the extracted rose products, owe their perfume to this alcohol because, owing to the solubility of phenyl ethyl alcohol in water, the steam distilled rose oils are almost entirely without it, and this much affects their odour as compared with extracted rose concretes. The alcohol is largely manufactured and such products vary very much in odour and keeping properties. The pure alcohol has a fresh rose-like odour, boils at 220° – 222° under 740 mm., the specific gravity is 1.0242, and the refractive index 1.53212.

Phenyl methyl carbinol.

This has been found as an acetic ester in oil of gardenia; it boils at 203° .

Cinnamic alcohol :— $\text{C}_6\text{H}_5 \cdot \text{CH} : \text{CH} \cdot \text{CH}_2\text{OH}$

This substance occurs in the free state and as esters in various balsams of Peru and Tolu, and is largely manufactured by the reduction of cinnamic aldehyde. It is a beautiful crystalline substance possessing a delicate, very persistent, odour reminiscent of roses and hyacinths. It melts at 33° , the boiling point is 258° under 760 mm., the specific gravity is 1.01 to 1.03 at 35° , and the refractive index is 1.3024 at 25° (superfused).

Phenyl propyl alcohol:—

This has been found as the acetic ester in cassia oil, and as the cinnamic ester in storax. It is a thick oil with an odour similar to cinnamic alcohol; it boils at 235° under 760 mm., the specific gravity is 1.007 and the refractive index 1.5283 at 20°C.

In considering the esters, it will be difficult to maintain a proper classification, as they are extremely varied, but the attempt will be made to deal with them in the same order as the alcohols.

Methyl anthranilate:—

This is the methyl ester of ortho amido benzoic acid.

It was discovered in neroli oil, and has also been found in numerous other flower oils, such as tuberose, ylang ylang, jasmin and gardenia. It has a very powerful odour similar to that of oil of neroli, and is manufactured on a large scale for use as a perfume material; when pure it is a white crystalline substance melting at 24° to 25°, and boiling at 132° under 14 mm. pressure, whilst the specific gravity is 1.168 at 15°, with the material in the super-fused condition. Its solutions have a beautiful blue fluorescence which is apparent in all the oils containing it. It gives with para dimethyl-amino-benzaldehyde in the presence of alcohol, a cinnabar red substance which crystallised from alcohol melts at 181°.

The methyl ester of methyl anthranilic acid:—

Has been found to the extent of 1.5 per cent. in oil of mandarins, and also in the oils of rue and orange blossoms. It is an oily liquid with a sweet odour resembling oranges; when cooled it crystallises and then melts at about 19°, it boils at 130° under 13 mm., the specific gravity is 1.1238 at 20°, and its solutions show a fine blue fluorescence.

Methyl benzoate:— $\text{C}_6\text{H}_5\cdot\text{COOCH}_3$.

This highly odorous ester has been found in the oils of ylang ylang, tuberose and cloves, and it is also manufactured on a large scale under the name of Niobe oil.

It is a liquid with a fragrant odour, boils at 199°, the specific gravity is 1.1026, and the refractive index 1.5170. The commercial article boils at 195°, and the gravity is about 1.103. This ester may be characterised by the crystalline compound which it forms with phosphoric acid as the benzoic esters of homologous alcohols form no such compound.

Methyl cinnamate:—

Is found in various balsams and in the oil of *Alpinia malaccensis*, and is also made artificially.

It forms a low melting crystalline substance having the following characters:— it boils at 256° under 745 mm., and at 263° under 760 mm. the melting point is 34°—36°, the specific gravity is 1.0663 at 40°, and the refractive index is 1.56816 at 35°. The commercial article is generally in the form of an oily liquid having a penetrating fruity odour, and the compound is of considerable value in the perfuming of toilet articles.

Methyl phenyl acetate:—

This ester has a powerful honey-like odour and is a liquid boiling at 220°. The ethyl ester boils at 226°, and the free phenyl acetic acid $\text{C}_6\text{H}_5\cdot\text{CH}_2\cdot\text{COOH}$, is a powerfully odorous crystalline substance melting at 76.5° and boiling at 262°.

Methyl salicylate:—

This ester is found in wintergreen leaves or in the sweet birch bark as an odourless glucoside called "gaultherin;" this glucoside decomposes under the influence of a ferment "betulase" setting free the methyl salicylate. For practical purposes, oil of winter green and oil of sweet birch are methyl salicylate, as they each contain about 99 per cent. of the ester. This substance is a colourless oil, having an intense wintergreen odour; it boils at 224°, has a specific gravity of 1.1819, and a refractive index of 1.5375. Much difficulty is experienced in distinguishing between natural oil of winter green and the artificial methyl salicylate and reference should be made to the *Jour. Amer. Chem. Soc.*, 1917, page 820.

Ethyl acetate.— $\text{CH}_3\cdot\text{COOC}_2\text{H}_5$

This occurs in the perfume of the magnolia. It is a liquid with a fruity odour, boils at 76, and has a specific gravity of 0.908.

Ethyl cinnamate :—

It is found in camphor oil, storax, and in a few other essential oils, it has a pleasant odour and is a liquid boiling at 271° with a specific gravity of 1.0498 at 20° , and a refractive index of 1.5590. When cooled it crystallises and then melts at 12° .

In connection with the esters of isoamyl alcohol, there has recently been published an investigation as to the actual composition of the odorous constituents of apples and this has led to the publication by F. B. Power and V. K. Chestnut of a formula which will reproduce the true odour of apples in foods and beverages: the following esters are used and should be in the highest state of purity whilst the quantities are by volume :—

The iso amyl ester of formic acid 10 parts.

The iso amyl ester of acetic acid 10 parts.

The iso amyl ester of normal caproic acid 5 parts.

The iso amyl ester of normal caprylic acid 1 part.

Acetaldehyde 2 parts.

Hexyl acetate :— $\text{CH}_3 \cdot (\text{CH}_2)_5 \text{OOC} \cdot \text{CH}_3$.

This ester occurs in the oil of heracleum giganteum, it has a fruity odour, boils at 169° , and has a specific gravity 0.890 at 10° .

Benzyl acetate :— $\text{C}_6\text{H}_5 \cdot \text{CH}_2 \cdot \text{COOCH}_3$

This has been found in the oils of jasmin, ylang ylang, and other flower oils, and although it has not a very intense odour, it is very important for the successful production of certain artificial floral perfumes; it is manufactured on a large scale and must always be examined for the presence of chlorine. When pure it is a colourless oil with a characteristic odour, it boils at 262° , the specific gravity is 1.057 and the refractive index is 1.5034. The commercial article generally falls within the following limits, the specific gravity 1.060-1.062, the refractive index 1.502-1.504, and it should contain at least 98 per cent. of esters and be soluble 1 in 6 or more of 60 per cent. alcohol.

Benzyl benzoate :—

This is a constituent of Peru balsam and also occurs in the oils of tuberose and ylang ylang. It is manufactured on a considerable scale, partly for use as a solvent for artificial musk and partly as a diluent and a fixing agent for the more volatile essential oils. It has a slight sweet odour

and gives a certain characteristic to blended perfumes. When absolutely pure it is a crystalline substance melting at 21° but, in general, it is a liquid, boils at 323° - 324° , and has a specific gravity of 1.124 and a refractive index of 1.5681.

Benzyl cinnamate :—

This is a natural constituent of storax, and the balsams Tolu and Peru, it is a crystalline substance with a characteristic sweet balsamic odour, it melts at 39° and decomposes at about 350° , the best commercial specimens melt at 31° - 33.5° , and contain from 96-98 per cent. of the true ester. Space does not permit of any further treatment of the ester group.

The Fatty Aldehydes.

Iso-amyl aldehyde :—

This has been found in sandalwood oil and is a liquid with a fruity odour, boils at 92.5° , and has a specific gravity of 0.8040 at 15° . It has been identified by means of its thio-semicarbazone, which melts at 52.5° .

Nonylic aldehyde :— $\text{C}_9\text{H}_{18}\text{O}$

Has been found in rose, orris, cinnamon, mandarin and lemon oils, it is a liquid, boiling at 80° - 82° under 13 mm., and on cooling crystallises and then melts at 5° - 7° , the specific gravity is 0.8277 and the refractive index is 1.42452.

Decylic aldehyde :— $\text{C}_{10}\text{H}_{20}\text{O}$

This has been found in orris, mandarin, neroli and other oils, it is a liquid boiling at 97° - 98° under 15 mm., and at 207° - 209° under 755 mm., and the specific gravity is 0.828-0.836, and the refractive index 1.4273-1.42977.

Duodecylaldehyde or lauric aldehyde :—
 $\text{C}_{12}\text{H}_{24}\text{O}$

Has been found in the pine needle oil from *Abies pectinata*, it is of special value when used together with the ionones. When added to α ionone in the proportion of 5 per cent. or to β ionone in the proportion of 10 per cent., it is stated to produce a highly natural violet perfume mixture. The aldehyde crystallises in leaflets melting at 44.5° , and it boils at 142° - 143° under 22 mm.

The above aldehydes are somewhat difficult to prepare and especially to preserve and use, but together with others which do not occur in essential oils, they have a great tendency to polymerise, and are usually

kept in 5 to 10 per cent. absolute alcohol solutions in fully filled bottles and in the dark.

The aromatic aldehydes.

The most important of these is:—

Benzaldehyde:— $C_6H_5 \cdot CHO$

This occurs in various seeds such as bitter almonds, and the seeds of the apricot and the peach. It is present in the form of a crystalline glucoside "amygdalin," which can be hydrolysed by the enzyme ferment "emulsin" the products of reaction being glucose, prussic acid, and benzaldehyde. The natural benzaldehyde may contain traces of prussic acid, but most of the benzaldehyde of commerce is made artificially and is a colourless to pale yellow liquid boiling at 178° and having a specific gravity of 1.050 and a refractive index of 1.5450.

Cinnamic aldehyde:—

$C_6H_5 \cdot CH : CH \cdot CHO$

This is found in the cassia oil which is derived from the leaves, leaf-stalks and young twigs of *Cinnamomum cassia*. The oil contains from 75 to 90 per cent. of cinnamic aldehyde and small quantities of cinnamyl acetate and beta-methoxy coumaric aldehyde. True oil of cinnamon called "Ceylon oil" is derived from the bark of the cinnamon tree. *Cinnamomum zeylanicum* also contains the aldehyde to the extent of 65 to 75 per cent. Often the leaves are distilled with the bark causing the oil of cinnamon to contain much eugenol, there has been detected in cinnamon oil such substances as pinene, phellandrene, cymene, eugenol, and the aldehydes benzoic, nonylic and hydrocinnamic, in addition to furfural and linalol. It should be mentioned that the oil derived from the cinnamon root contains eugenol, safrol, camphor, benzaldehyde and esters of benzoic acid. Pure cinnamic aldehyde is a colourless to yellow, oily liquid, having a characteristic odour. It boils with decomposition from 247° – 252° , the specific gravity is 1.054–1.058, and the refractive index is 1.6195.

Ortho-methoxy cinnamic aldehyde:—

$C_6H_4 \begin{cases} OCH_3 \\ CH : CH \cdot CHO \end{cases}$

This has been found in cassia oil as a yellow crystalline compound melting at 45° and boiling at 295° . The para isomer is a constituent of estragon oil, it boils at 170° under 14 mm. and has the specific gravity 0.137.

Cumic aldehyde: or isopropyl benzaldehyde:—

$C_6H_4 \begin{cases} C_3H_7 \\ CHO \end{cases}$

This has been found in cumin, baldo leaf, cassie flower and certain eucalyptus oils, it is a powerfully odorous liquid boiling at 235.5° and it has a specific gravity of 0.982.

Salicylic aldehyde:—

$C_6H_4 \begin{cases} CHO (1) \\ OH (2) \end{cases}$

Has been found in the oils of the spirocea family and is also prepared artificially. It is an almost colourless fragrant oil, having the odour of meadowsweet, it boils at 197° and has a specific gravity of 1.1731.

Anisic aldehyde:—

$C_6H_4 \begin{cases} CHO (1) \\ OCH_3 (2) \end{cases}$

It is a natural constituent of oil of aniseed and fennel oil and is prepared on a large scale, and also obtained as a by-product from the manufacture of coumarin. It is a liquid boiling at 246° , the specific gravity is 1.126–1.129 and the refractive index is 1.5725.

Vanillin—the methyl ester of protocatechuic aldehyde.

This very important substance is found in the vanilla pod, and the vanilla of commerce is the dried and prepared pod of several varieties of a climbing orchid, of these there are eight well-known varieties that produce marketable pods, of which five are found in Java; probably the three best known are *Vanilla planifolia*, *V. sylvatica* and *V. pompona*. The vanilla plant is a native of Central and South America and is cultivated in Mexico, Brazil, Honduras, Guadeloupe Réunion, Mauritius, the Seychelles, Java, Tahiti, the South Sea Islands, Polynesia and in Tropical Queensland. The beans undergo a special treatment which brings about the formation of the vanillin. The artificial production of vanillin was one of the triumphs of organic chemistry so far as the perfume industry is concerned and to-day scores of processes are known whereby it can be formed. It is largely made from eugenol, a phenol found in oil of cloves, etc. When pure, vanillin forms white crystals which melt at 81° – 82° , and distilled in a current of carbon dioxide, it boils at about 285° .

Heliotropin or piperonal or the methylene ether of protocatechuic aldehyde.

This occurs in certain varieties of vanilla and also in oil of spiroea and can be made from the alkaloid piperine which occurs in pepper but is always manufactured from safrol. It is a white crystalline substance melting at 37° and boiling at 265° . It is curious to record that although it is an aldehyde, it does not reduce silver nitrate solution.

Furfural :—

This is an aldehyde of rather special constitution, it is found in many essential oils, such as ambrette, East Indian sandalwood, petitgrain, clove, vetiver and many others, and is generally accompanied by traces of methyl alcohol and diacetyl. It is a liquid boiling at 160.5° under 742 mm., and has a specific gravity of 1.594. α methyl furfural :—

has been found in clove oil and is a liquid boiling at 185° .

The phenols and their derivatives.

Of the many phenolic compounds which occur in essential oils, those containing either the allyl or the propenyl group are of special interest. No attempt will be made to arrange these phenols in any particular order, but for reasons which will be apparent later the first phenol to be dealt with is :—

Estragol—methyl chavicol or iso anethol :—

This para-methoxy-allyl-benzene occurs in shervil and basil oils, whilst the isomeric :— anethol or para-methoxy-propenyl-benzene

is an important constituent of aniseed oil. In reality, estragol is changed into anethol by boiling with alcoholic potash, and it must be remarked that this isomeric change is of enormous technical importance in connection with the manufacture of vanillin from eugenol and of heliotropin from safrol.

Para-Cresol :—

This substance is found in the oils of cassia and jasmin, it is a crystalline compound melting at 36° and boiling at 199° .

Para-Cresol methyl ether :—

occurs in ylang ylang oil, it is a liquid boiling at 176.5° and has a specific gravity of 0.9757 and is manufactured artificially for use in perfumery.

Meta-Cresol :—

Has been found in myrrh oil and is a liquid boiling at 201° .

Phlorol or ethyl phenol :—

It occurs in oil of arnica as an isobutyl ether and is a liquid boiling at 226° .

Guaiacol or the methyl ether of catechol :—

This monomethyl ether of ortho-dihydroxy-benzene has been found in celery oil. It possesses a very characteristic odour, and when pure is a crystalline substance melting at about 33° , but the commercial article is frequently liquid, and boils at 200° . This guaiacol is a raw material for the manufacture of vanillin and some of its compounds are of considerable medicinal interest.

The ethyl ether of hydroquinone :—

This has been isolated from star anise oil and forms colourless pearly needles, which melt at 64°.

Methoxy-methyl-salicylate or p-methoxy-beta-methyl-resorcyate :—

This has been called "primula camphor" and is contained in the essential oil of primula; it is a crystalline substance melting at 49°.

The Dimethyl ether of pyrogallol :—

This has been isolated from schei oil, it is crystalline and melts at 51°.

Phloracetophenone-dimethyl ether :—

This substance has been isolated from "Ngai camphor," which is obtained by distillation from the plant *Blumea balsamifera* and has also been found in the oil from *Xanthoxylum Aubertia*. At this point mention should be made that Thoms, whilst investigating the root oil of *Fagara xanthoxyloides*, extracted from the shells a solid substance melting at about 128°, from which two substances were isolated, e.g., Xanthotoxin, a powerful fish poison, melting at about 146°, and Bergaptene, melting at about 191°, this latter is also an important constituent of bergamot oil. The two substances are isomeric, but whilst xanthotoxin is a derivative of pyrogallol, the bergaptene is a derivative of phloroglucinol :—

Xanthotoxin.

Bergaptene.

Paenol or oxy-methoxy-acetophenone :—

This is found in the root of *Paeonia Montana*, as a glucoside, which on hydrolysis gives the paenol as a crystalline substance with an aromatic odour and melting at 50°.

Carvacrol :—

This is isomeric with thymol and carvone :—

It has been found in the oils of *origanum hirtum* and *Satureja hortensis* and in wild bergamot, whilst Crete origanum oil contains about 55 per cent. of this phenol. It is a thick liquid boiling at 237°, the specific gravity is 0.980, and on cooling it crystallises and then has a melting point of 0.5°. Although it resembles thymol it can be distinguished therefrom by its alcoholic solution giving a green colouration with ferric chloride, whilst thymol gives no colouration. The phthalein of carvacrol can be used as an indicator giving a deep blue colour, and, further, has a purgative action similar to phenolphthalein.

Thymol, methyl-iso-propyl phenol or iso-propyl-meta-cresol.

This important and valuable substance occurs in oil of thyme to the extent of about 20 per cent. and in ajowan oil to the extent of 40-55 per cent. From such oils the thymol is isolated and this industry is now well established in this country. It forms large white crystals, which melt at about 51° and boil at about 234°, its powerful antiseptic and germicidal properties render it of great value.

The methyl ether of thymol :—

Is found to the extent of about 10 per cent. in sampline oil and in the oil from *crithmum maritimum*, it is a liquid boiling at 217° and having a gravity of 0.954 at 4° .

Thymoquinone :—

This has been isolated from the oil of wild bergamot (*Monarda fistulosa*) and also in *thuya articulati*, and is generally associated with thymo-hydroquinone. It is a crystalline substance melting at 48° .

Thymo-hydroquinone :—

Is a constituent of wild bergamot and Algerian fennel oils, and forms colourless crystals melting at 145° and boiling at 290° .

The dimethyl ether of thymo-hydroquinone. This occurs in oil of arnica root as a liquid boiling at 248° - 250° and with a gravity of 0.9913 at 20° .

Chavicol, p-oxy-allyl-benzene :—

Is a constituent of the essential oils of bay and betel, and is a liquid boiling at 237° with a gravity of 1.033.

Estragol or methyl chavicol or iso-anethol :—

Has been mentioned before and is found in estragon, chevril and basil oils, it is a liquid having a characteristic anise odour, boils

at 216° and has a specific gravity of 0.9663 at 15° and a refractive index of 1.51966 at 20° . The estragon oil is used in the manufacture of mustards, relish sauces, and table vinegars and for various culinary purposes.

Allylpyrocatechol :—

Has been identified together with chavibetol in Java betel oil, it is a crystalline compound with an odour resembling creosote and melts at 49° .

Chavibetol or betel phenol :—

Is found as mentioned above and is an oil having the characteristic betel odour, it boils at 255° and has a gravity of 1.069.

Anethol, the methyl ether of p-propenyl benzene :—

This is an important constituent of aniseed and fennel oils, whilst star anise oil contains it to the extent of about 80 per cent. It forms white crystals which melt about 23° and have a congealing point of 21° - 22° , and the boiling point is 235° , whilst the specific gravity is 0.984-0.986 at 25° .

Eugenol, the methyl ether of allyl dioxy-benzene :—

This is a constituent of oil of cloves in which it occurs to the extent of 85-95 per cent., and it is also found in the oils of allspice, bay and cinnamon leaves. The phenol has been found in *Geum urbanum* in the form of a glucoside "Geine," which can be split by the ferment "Gease" which is found in the same plant. Much eugenol is manufactured from oil of cloves

and is a colourless liquid with a characteristic clove odour, boils at 248° , the gravity is 1.072 and the refractive index 1.5439. It is the raw material for making vanillin, and is much used as an antiseptic.

Eugenol methyl ether:—

Is a constituent of the oils of *Evodia simplex*, cassie, ylang ylang, citronella, and Canadian snake root. It is a liquid with a clove odour, boils at 249° , the gravity is 1.055, and the refractive index 1.5373.

Iso-eugenol:—

Is a constituent of nutmeg and ylang ylang oils, and is prepared on a large scale from eugenol. As ordinarily prepared, it is a liquid with odour reminiscent of cloves and carnations, it boils at 261° and has a gravity of 1.090 and a refractive index of 1.5680—1.5728. When sunlight acts upon iso eugenol dissolved in alcohol containing hydrochloric acid, a polymerisation into a crystalline substance di-isoeugenol melting at 180° , takes place.

The methyl ether of iso-eugenol:—

This is a constituent of the oil of *asarum arifolium*, and is a liquid boiling at 263° .

Safrol, the methylene ether of allyl dioxybenzene:—

This is found in Japanese star anise oil from the fruit of *Ilicium Religiosum*, and it must be pointed out that this oil differs from the Chinese star anise oil as it only contains a trace of anethol mixed with the safrol. Safrol is also found in sassafras

oil, but is manufactured on a very large scale from camphor oil to serve as the raw material for making heliotropin. It is a liquid boiling at 233° , the specific gravity is 1.106, the refractive index is 1.5380.

Iso-safrol, the methylene ether of propenyl dioxybenzene:—

It is a constituent of ylang ylang oil, but is manufactured by the isomerisation of safrol and by a simple series of reactions is converted into heliotropin. It is a liquid boiling at 254° , the gravity is 1.127 and the refractive index is 1.5800.

Elemicine:—

Has been isolated from manilla elemi oil, and is a liquid boiling at 144° — 147° under 10 mm., and has a density 1.063 at 20° .

Apiol:—

Is a constituent of German oil of parsley seed, and is also found in Matico oil; it is crystalline, melts at 30° and boils at 294° under 760 mm.

Anethol apiol or dill apiol:—

This occurs in Matico oil and is a liquid boiling with decomposition at 285° .

Myristicine:—

This is a constituent of nutmeg parsley and certain other oils, it boils at 149.5° under 15mm., and the gravity is 1.1425 at 19° .

Diosphenol :—

It has been stated that Buchu oil consists of two main constituents, the solid diosphenol and a liquid. Diosphenol is crystalline, melts at 83° — 84° and boils at 109° — 110° under 10 mm.

HETEROGENEOUS COMPOUNDS.

Coumarin :—

This is found naturally in many plants, though it is well-known that such plants do not exhale the odour when fresh and unbruised. When dried or injured, the odour becomes apparent and this is the case with all the coumarin-producing plants such as *Anthoxanthum odoratum*, the sweet-scented vernal grass and other grasses which impart the characteristic odour to hay. It is also found in the *Laitris odoratissima* and *Laitris spicata* or deer's tongue and in the *Angraecum Fragrans*, *Melilotus fragrans* and *Asperula odorata*, or Woodruff. The chief natural form of coumarin is the Tonco, Tonka or Tonquin bean, and these are the seeds of the *Dipteryx odorata*. The real sources of the bean are the tropical countries of South America, principally in the valleys of the Orinoco, Caura, and Cuchivero rivers of Venezuela and in parts of Colombia. In Venezuela the centre of the industry is Ciudad Bolivar. The seeds require treatment in order to bring about the formation of coumarin; actually about 3 per cent. of coumarin is contained in the bean. Much coumarin is made with salicylic aldehyde as the starting material and the manufacture of this aldehyde is not very easy. Pure coumarin forms colourless crystals melting at 68° and boiling at 289° .

Cineol or eucalyptol :—

This very important substance is found in considerable quantity in the oils of Cajuput, Eucalyptus and wormseed and also in smaller quantities in the oils of camphor, cinnamon, lavender, laurel rosemary, sage and spike. It is a liquid boiling at 176° and having a specific gravity of 0.928 to 0.930, and a refractive index of 1.458-1.459. It forms compounds with several widely different substances, such as arsenic acid, phosphoric acid, resorcinol, and ortho cresol, from this last cresinol is obtained.

Ascaridol $\text{C}_{10}\text{H}_{16}\text{O}_2$.

This substance is allied to cineol and is found in the oil of *Chenopodium* to the extent of about 70 per cent., it is a liquid boiling at 80° — 84° under 5 mm. pressure and decomposes violently on heating to 130° — 150° , becoming a paraffin hydrocarbon, it has a specific gravity of 1.008, a refractive index of 1.474, and an optical rotation of -4° to -5° .

Of the compounds containing nitrogen which occur in essential oils, hydrocyanic acid is the simplest. This acid is found, together with benzaldehyde, in the oils of almonds, cherry-laurel and wild cherry bark, and its properties are too well-known to be mentioned here.

Allyl cyanide :— $\text{CH}_3 \cdot \text{CH} : \text{CH} \cdot \text{CN}$

This has been discovered in the essential oils of mustard and horseradish, it is a liquid boiling at 120° — 123° . The nitrile of phenyl acetic acid $\text{C}_6\text{H}_5\text{CH}_2\text{CN}$ boils at 231.5 and has been found in the oils of *Tropaeolum majus* and *Lepidium sativum*, whilst the nitrile of phenyl propionic acid, $\text{C}_6\text{H}_5\text{CH}_2\text{CH}_2\text{CN}$, boiling at 261° , is a constituent of nasturtium oil.

Some very volatile nitrogen and sulphur compounds such as ammonia and trimethylamine, are sometimes produced during the distillation of certain essential oils and sulphuretted hydrogen is always formed

during the steam distillation of caraway seeds.

Oil of black mustard contains carbon disulphide and American peppermint dimethyl sulphide, whilst allyl sulphide is a constituent of oil of garlic.

Allyl iso-thio-cyanate, $C_6H_5 \cdot N:C:S$, is an important constituent of mustard oil, and is formed by the decomposition of a glucoside, it is also made artificially and is a liquid boiling at 151° . Several similar compounds are found in the oils of the mustard family.

A compound of quite a different character viz., pyrrol,

is found in Paraguay petitgrain oil and is a liquid boiling at 131° .

Pyridine has been isolated from the oil from roasted coffee.

Indol :—

This is known to be a constituent of the oils of neroli and jasmin, and is present in the odorous emanations from many members of the citrus genus and other flowers. The following test will show the presence of indol in flowers :—Cotton wool, soaked in a saturated solution of oxalic acid is placed on the bottom of a covered glass vessel and a clock glass containing the fresh flowers is placed on this. The cover is securely fixed on the apparatus, allowed to stand in the light for 24 hours. In the presence of indol parts of the cotton will show a violet to reddish shade. In another test, a filter paper moistened with a solution of vanillin in a mixture of strong hydrochloric acid and alcohol is suspended in contact with the vapours from the flowers, when traces of indol cause a violet colouration, and this test also detects skatol. Indol melts at 52° , boils at 254° and has a disagreeable smell.

Skatol :—

This β methyl indol occurs in certain woods, such as celtis, reticulosa. It has a

most offensive smell, is crystalline, melts at 95° and boils at 285° .

In recent years it has been obvious that research in every direction has been actively in progress and whilst much work has been done of a rather academic character, on the terpene derivatives, there has been a distinct advance in our knowledge of the constituents of essential oils. Much work has been done on the manufacture of purely synthetic odorous substances, such as phenyl acetaldehyde, and the ionones, whilst the art of sophistication has not been neglected, and the analyst is required to be continually alert. The application of optical methods, such as the measurement of rotations and indices of refraction, has been more and more utilised, and the data therefrom have rendered the path of the adulterator exceedingly difficult. In connection with this industry at home, the manufacture of flavouring esters has been well developed, but much remains to be done in insuring the absolute uniformity of the products offered as this is of paramount importance to the user, who has to produce comestibles always of uniform odour and taste. Once again emphasis must be placed on the necessity for producing the widest possible range of substances used in the perfume industry and manufacturers now in the front rank must see that their analysts do not allow any product to pass from their works to the consumer without the certainty that the product is as pure as they represent it to be; a few careless mishaps can do untold harm to this rising industry.

The Empire contains within its confines such varieties of climate and soil that it is quite possible for it to provide every kind of raw material and essential oil, and the Colonies, etc., should be urged and helped in every possible way to develop to the fullest extent their present resources, and to experiment with the introduction of plants suitable to their particular district. There can be no doubt that by a proper survey of the Empire's resources, carried out in a thorough manner, it will be discovered that the British Empire alone is able to provide British manufacturers with all the materials they need for a successful essential oil industry, and all the ramifications therefrom, and, further, our young chemists must have brought before them the importance of this branch of chemical industry. There already exists an ably conducted Journal, *The Perfumery and*

Essential Oil Record, entirely devoted to this industry, and this should be supported in every possible way, and the researches should be as far as possible published in such a special organ, as the scattering of publication does not conduce to strength; and, further, the industry should combine to form a research association, governed by thoroughly competent members of firms already engaged in the industry, and this association should obtain the power which will enable it to approach the Government as an authoritative body on every matter connected with every branch of this great industry.

NOTES ON BOOKS.

RADIO-ACTIVITY AND RADIO-ACTIVE SUBSTANCES. By J. Chadwick, 1921.

FILTRATION. By T. Roland Wollaston. 1922.

INDUSTRIAL NITROGEN. By P. H. S. Kempton. 1922. These form part of Pitman's series of Technical Primers. 2s. 6d each, net. London: Sir Isaac Pitman and Sons, Ltd.

Radio-activity and radio-active substances as a title for a technical primer, leads us to expect a study of applied or industrial aspects; as, for example, the associated radium salt and zinc sulphide, or like preparations, which did us such good service during the war as a means of locating positions in darkness, the use of radium for stemming malignant degenerations of tissue, also other medical applications, various amplifiers or devices that render transatlantic telephony possible and which are directly or indirectly consequent on researches as to radio-activity, the use of the natural stock of the outcome gas helium in aerostation, and, indeed, many other applications actual or in prospect.

The long sub-title and the preface, however, prepare us for a theoretical treatise, mainly on the nuclear aspect of the atom.

Figure 2 on p. 7, gives, it is said, "a rough idea of the general build of the nucleus atom," and the figure rather suggests a solar system with eleven planets in two circular orbits, but we are uncertain as to the author's views on the vexed question of rotation. Nevertheless, we are confidently told (p. 6) that "since the atom, as a whole, is neutral, there must be a positive charge associated with the atom, equal in amount to the sum of the negative charges"; this being repeated with slight variation on p. 7.

Attractive as this concise dictum may appear to some, we may suggest that an exactly balanced polarity, or neutral condition of each atom, is merely a conjecture; indeed, a conjecture based on the conjecture that atoms exist as such. Admitting both conjectures to be true,

speculations regarding electrical or other equilibrium should include a consideration of conditions like those touched on by Sir J. J. Thomson in *NATURE*, November 6th, 1919, p. 225; especially as to the inter-relations of mass and charge, mass and velocity; also Thomson's view that in matters of atomic equilibrium the rule of inverse squares does not always hold good, and we may have a change from attraction to repulsion at definite distances. Mention may be made of Professor Harkins's letter in *NATURE* of April 22nd, 1920, and the list of references which he gives. The reader of the book under notice will realise that the somewhat various and nebulous conjectures of the present time tend towards replacing the ancient doctrine of a protyle by a view that the fundamental physical constituents are two, and when associated they give rise to the Daltonian combining units, groups, or perhaps better "atomoids."

"Filtration" is eminently practical, thorough and clearly expressed. The author, by a judicious economy of words, and the avoidance of all superfluities, makes it a good first textbook as regards water purification, as also testing, and the drawings of the essential features of representative filtration systems are admirable. Mr Wollaston includes the essential facts as regards filter-presses, centrifuges, oil filters, spray screens for air filtration, and the means of bringing about an electrostatic deposition of dust. Like all good technical books, Mr. Wollaston's primer is virtually much more comprehensive than in actual fact, by reason of the many references in the text, and a thoughtfully considered bibliography.

"Industrial Nitrogen" is, in the main, a booklet on the methods of converting atmospheric nitrogen into industrially serviceable products; as nitrates, ammonia, or cyanogen compounds, and the general reader may gather from it many interesting first notions. There appears to have been a somewhat hasty reading of the proofs: hence there is not in every case that strict and exact relation between chemical words and their meanings, which is so essential to the making of a satisfactory technical primer. Thus "Chile saltpetre" (p. 7) is not ideal as the commercial name of potassium nitrate, and on p. 84, there is a tabulation of aniline colours, but chemical names, as given, would be the better for revision. For example, pararosaniline is not magenta, in the strict sense of the term, but a colourless substance which may yield a magenta.

DESIGN OF THE SENTENCE FOR TECHNICAL USE.

A comparative study of the three technical primers from the standpoint of that art of arts, the exact use of words and phrases, may be opportune.

Mr. Wollaston's book on filtration appears to us to be the work of one who takes a keen personal interest in language, and as an outcome of this interest he contrives to make his sentences and meanings clear and definite, without any appearance of pedantry.

Mr. Kempton is at times notably metaphorical; for example, on p. 10 he refers to "harnessing this inert chemical monster nitrogen to the chariots of war," and the word "key" figures rather obtrusively and variously as a simile. In the figurative sense Mr. Kempton appears to recognise several master keys, as he terms nitric acid "one of the master keys to the materials of our modern civilisation" (p. 62).

Dr. Chadwick may have been influenced by the publisher's announcement as to the usefulness of the series to "the busy practical man," and in striving towards adaptation to this standard, he appears to have drifted too deeply into that language of London's busy artificers, and of a growing school of metropolitan newspaper reporters, which is commonly known as the dialect of London; one characteristic being a loss of nearly all the old preterite and aorist forms, many of which are still fully current in the Midlands and Northward (see p. 26 of MacBride's "London's Dialect," Priory Press, Hampstead, 1910). Imperfect past forms, repeated or multiplied in the same period or sentence sometimes give to that which ought to be a gnomic aorist, an aspect which to the serious student may appear to be something beyond a pluperfect: thus a well-meant effort to make matters clear to those of immature scholarship may mislead those of riper scholarship; unless the reader happens to have such previous knowledge of the laboratory facts, as may cause him unconsciously (or by a kind of reflex action) to adjust himself to the vague or non-lucid language.

For example, on p. 1 of Dr. Chadwick's book he tells us that "—— uranium salts emitted spontaneously a radiation which was capable ——," and that "—— radiation from uranium also possessed the property ——." The full text of these sentences taken literally suggests that the emissive quality is a transient condition which merely held good when Becquerel made his observations, but the actual fact is otherwise; the emissive condition being independent of temperature, pressure, chemical stress or anything even remotely analogous to spontaneity, contingent action, or freewill; indeed, depending on an immanent property of uranium, effective as regards past, present and future; or as long as any trace of the original uranium remains.

During some three thousand years it has been a custom of plain non-emotional or non-poetical writers to use the present tense of the verb to express the sense of the gnomic aorist or the aorist indicative: and this quite irrespec-

tive of the existence or non-existence of definite aorist forms in the language used. Much may be said in favour of this concise and usually lucid mode of expression. Harris (Hermes, 5th edition, London, 1794, p. 124) illustrates its application to verse by quoting Milton's line:—

"Millions of spiritual creatures walk the earth." That is to say they walked, walk now, and will walk. The alternative course, or use of many finely adjusted and well-considered augmentations to the conjugations of the verbs is touched upon by Breal (Semantics, Mrs. Cust's English version, Heinemann, 1900, p. 75); not in relation to any question of convenience in respect to modern use, but rather as illustrating the intelligence of the Athenian masses "in overcoming difficulties which, in every art, the material opposes to the workman."

Metaphor and what one may term literary decorations of the florid kind, appear to be for the most part incongruous in technical and scientific writings much in the sense that the "Fine Art Microscope" of Messrs. Parkes and Son, shown in the Exhibition of 1862 (figure of Dolphin, or like, embodied in the stand of a microscope) was denounced by the jurors as "an incongruous and uncommendable monstrosity" (Juror's reports, issued by the Society of Arts, Class XIII. p. 23). In connection with this view it is interesting to note that the immortal master of metaphor, Milton, in his History of Britain, adopts a rigidly plain style, but so perfect as regard lucidity and the grammatical forms, that should the time ever come for a detailed study of the design of the sentence as adapted to technical and scientific use, this work may be of material use as a first pattern.

THE EMBROIDERY AND DRAWN WORK INDUSTRY OF THE CANARY ISLANDS.

The embroidery and drawn-work industry of the Canaries, though not a very important one, holds an interesting position in the trade of the islands. Teneriffe embroidery has been known widely for many years and there is a constant, though small demand, for it. Local statistics show that 113,935 pounds of embroideries, drawn work, and lace were shipped to 15 countries in 1920.

All this work, writes the United States Vice-Consul at Teneriffe, is done by hand and is undertaken by women in their homes in the same manner as the lace industry is carried on in Belgium. The larger part of the work is done on orders received by firms specialising in the placing of orders locally and the shipping of the manufactured articles to the purchaser. These jobbers distribute the work among the women, furnishing them with the necessary cloth and thread, and sometimes also with the design, paying them for their labour.

Apparently the commission charged by these jobbers is quite reasonable, as this method of doing business seems to be satisfactory to the foreign importer.

The cloth used ranges from all cotton to cotton and linen, pure linen, and silk. Barcelona supplies most of the cotton cloth; the cotton-linen, all-linen, and silk cloths largely come from Great Britain. Formerly Belgium was the chief supplier of pure linen cloth. Cotton thread is used and is brought from Barcelona, Great Britain, and Mulhouse (Alsace-Lorraine), though imports from the last named centre have declined considerably since the war.

The industry comprises three distinct kinds of work: embroidery, which consists of designs worked on cotton, linen, or silk cloth; drawn work, which consists in drawing threads out of the cloth and, with a needle, working in a sort of lace in the space left; and lace, which is made on a small cushion by hand. (No machine-made lace is produced in these islands.) The embroidery work is done in the island of La Palma, the drawn work in Teneriffe, and the lace in Lanzarote. Orders are usually placed in the spring and summer, so that the work may be completed by autumn, the best season for selling these articles in the northern countries. There is no standard price for the finished pieces; when orders are scarce prices are lowered to attract buyers, and when orders are plentiful prices rise accordingly.

UTILISATION OF COAL WASTE ON GERMAN RAILWAYS.

Germany's greatest user of coal is the Federal Railway, which formerly was able to utilise only 55 to 70 per cent. of its combustible material, the remainder (cinder and ashes) having been regarded as worthless. In order to make use of this waste, which is said to contain 50 per cent. or more combustible material, about two years ago the railway adopted the Meguin system of recovering coal from ashes. According to a report by the United States Consul at Frankfurt on Main, thirteen large works, with a capacity for handling 420,000 tons of cinders and ashes annually, are now in operation or under construction. The amount of pure coke obtained is estimated at 164,000 tons, with an average calorific value of 5,500 units, compared with 7,000 units for good hard coal.

The fine coke, with the addition of fine coal and hard pitch, is used in making briquettes, about 74,000 tons of coke briquettes being thus obtained, with a calorific value of 6,500 units. In addition to this, 256,000 tons of non-combustible clean slag are obtained; this serves for the manufacture of 130,000,000 slag stones, which are employed in building and possess the good qualities of both brick and "schwemmstein" (a kind of sandstone).

*MEETINGS OF OTHER SOCIETIES FOR THE ENSUING WEEK.

- MONDAY, NOVEMBER 6.** University of London, at the London School of Economics, Houghton Street, Aldwych, W.C., 6 p.m. Prof. Eugene Borel, "The Position of Switzerland in International Law." British Architects, Royal Institute of, 9, Conduit Street, W., 8 p.m. Opening Address by the President. Transport, Institute of, at the Institution of Electrical Engineers, Savoy Street, Victoria Embankment, W.C., 5.30 p.m. Sir William Acworth, "British Railway Operating Statistics and their Lessons." Engineers, Society of, at the Geological Society, Burlington House, Piccadilly, W., 5.30 p.m. Mr. E. K. Turner, "The Atlantic Cruise of H.M. Airship R. 34." Chemical Industry, Society of (London Section), at the Engineers' Club, 89, Coventry Street, W., 8 p.m. Dr. E. F. Armstrong, "Some Problems in Chemical Industry."
- TUESDAY, NOVEMBER 7.** Civil Engineers, Institution of, Great George Street, S.W., 6 p.m. Address by the President, Dr. W. H. Maw. Metals, Institute of (Birmingham Section), Chamber of Commerce, New Street, Birmingham, 7 p.m. Mr. W. R. Barclay, "Nickel, its Properties and Uses." Alpine Club, 23, Savile Row, W., 8.30 p.m. Brig-General the Hon. C. G. Bruce, "Outline of the 1922 Everest Expedition." Anthropological Institute, 50, Great Russell Street, W.C., 8.15 p.m. Prof. Sir Arthur Keith, "An Account of Mr. G. Despot's Excavation of the Cave of Ghar Dalam, Malta, and an Exhibit of two teeth of Neanderthal Man found there."
- WEDNESDAY, NOVEMBER 8.** Geological Society, Burlington House, Piccadilly, W., 8 p.m. Industrial League and Council, Caxton Hall, Westminster, S.W., 7.30 p.m. Mr. H. H. Elvin, "Education as a Function of Management." Public Health, Royal Institute of, 37, Russell Square, W.C., 4 p.m. Mrs. Margaret Rorke, "The Problem of the Syphilitic Child." Botanic Society, Regent's Park, N.W., 3 p.m. Prof. R. R. Gates, "Modern Advances in Genetics." St. Paul's Ecclesiastical Society, 7, St. Andrews Street, Holborn, E.C., 8 p.m. Mr. P. M. Johnstone, "Romanesque Architecture in the South Western Counties." Metals, Institute of (N.E. Coast Section), Armstrong College, Newcastle-on-Tyne, 7.30 p.m. Mr. O. Smalley, "Moulding Sands." (Joint meeting with the Institute of British Foundrymen.) University of London, University College, Gower Street, W.C., 6.15 p.m. Mr. A. W. Flux, "Foreign Exchanges: Effects of War on the Exchanges." The Balancing of International Payments. (Lecture I.) Electrical Engineers, Institution of, Savoy Place, Victoria Embankment, W.C., 6 p.m. (Wireless Section). Messrs. R. L. Smith Rose and R. H. Barfield, "The Effect of Local Conditions on Radio Direction-Finding Installations."
- THURSDAY, NOVEMBER 9.** Royal Society, Burlington House, Piccadilly, W., 4 p.m. Metals, Institute of, at the Institution of Marine Engineers, 85, Minories, E., 8 p.m. Prof. H. C. H. Carpenter, "The Production of Large Crystals of Aluminium and some of their Properties."
- FRIDAY, NOVEMBER 10.** Astronomical Society, Burlington House, Piccadilly, W., 5 p.m. Physical Society, Imperial College of Science, Imperial Institute Road, South Kensington, S.W., 5 p.m. Timber Trade Lectures, at the London Chamber of Commerce, Oxford Court, Cannon Street, E.C., 6.30 p.m. Mr. H. Stone, "Duhamel, Pioneer in the Study of Wood." Metals, Institute of (Sheffield Section) The University, Sheffield, 7.30 p.m. Address by the Chairman (Prof. C. H. Deach).

Announcements intended for insertion in this list must be received at the SOCIETY'S Office not later than the Monday of the week preceding the Meeting.

*For Meeting of the ROYAL SOCIETY OF ARTS, see page 848.

Journal of the Royal Society of Arts.

No. 3,651.

VOL. LXX.

FRIDAY, NOVEMBER 10, 1922.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C.(2)

NOTICES.

NEXT WEEK

MONDAY, NOVEMBER 13th, at 8 p.m. (Special Meeting.) JOHN SLATER, F.R.I.B.A., Member of the Council of the Society, "The Strand and the Adelphi: their Early History and Development." LORD ASKWITH, K.C.B., K.C., D.C.L., Chairman of the Council and a Vice-President of the Society, will preside. (The paper will be fully illustrated with lantern slides.)

WEDNESDAY, NOVEMBER 15th, at 8 p.m. (Ordinary Meeting.) Overingenieur DR. SIGURD SMITH (Charlottenlund, Denmark), "The Action of the Beater in Paper Making, with special reference to the Theory of the Fibre Board and its application to Old and New Problems of Beater Design." Captain W. E. NUTTALL, M.B.E., Chairman of the Technical Section, Papermakers' Association, will preside. (Lantern illustrations.)

FRIDAY, NOVEMBER 17th., at 4.30 p.m. (Indian Section). J. W. MEARES, C.I.E., M.Inst.C.E., M.I.E.E., Member of the Institution of Engineers (India), "The Development of Water Power in India." SIR THOMAS H. HOLLAND, K.C.S.I., K.C.I.E., LL.D., D.Sc., F.R.S., F.G.S., Rector of the Imperial College of Science and Technology, will preside.

Further particulars of the Society's meetings will be found at the end of this number.

REPRINT OF CANTOR LECTURES.

The Cantor Lectures on "The Mechanical Design of Scientific Instruments," by Professor Alan F. C. Pollard, F.Inst.P., A.M.I.E.E., have been reprinted from the *Journal*, and the pamphlet (price 2s.) can be obtained on application to the Secretary, Royal Society of Arts, John Street, Adelphi, W.C. 2.

A full list of the lectures which have been reprinted and are still on sale can also be obtained on application.

EXAMINATIONS, 1922.

It is gratifying to note that the popularity of the Society's examinations, which has been established for many years, is steadily increasing. In 1919, the first year after the war, the number of papers worked was 31,132; this figure increased in 1920 to 49,390; in 1921 to 51,267; while this year it again broke all records by rising to 56,775.

The principal reason for this growing popularity is, no doubt, to be found in the ever-increasing number of students who are seriously pursuing courses of study in commercial subjects and modern languages. For these the London County Council and the Local Education Authorities throughout the country are now providing facilities for study on an immense scale. The Society's Examinations furnish them with a valuable stimulus and a definite goal, while the certificates gained by successful candidates offer reliable evidence of the proficiency which they have acquired in their respective subjects. The value of these certificates is becoming every year more and more widely known. A very considerable number of the larger business firms now directly encourage their employees to enter for these Examinations, and many grade their junior staffs according to the successes which they obtain.

With a view to encouraging this movement a circular letter, signed by Lord Askwith, Chairman of the Council, and Sir Philip Magnus, Bt., Chairman of the Examinations Committee, has recently been addressed to a large number of firms throughout the country, urging them to give facilities to their junior employees to attend Evening Classes with a view to furthering their education and to their taking recognised examinations at the end of each session. Many manufacturing and commercial firms in London and the provinces already make valuable concessions of this nature to their staffs, and it is hoped that their example may be more widely followed.

It is often the case that young people on leaving school are by no means eager to pursue their education further, and it is only after a lapse of years that they realise they have lost valuable time in not taking up the study of various commercial subjects not included in the school curriculum. Advice and encouragement in such matters from a principal or manager in the office does much to correct this attitude of mind in the young clerk, and experience shows that such advice often carries more weight than parental influence. Employers can, in this way, do much to raise the efficiency and usefulness of their clerks and thus benefit themselves and the community at large.

It is, of course, true that much of the work in an office is specialised and peculiar to the firm in question, but it is nevertheless the fact that an employee who, in his spare time, acquires a good knowledge of Book-keeping, or Shorthand and Typewriting, or a Modern Language, as well as a theoretical knowledge of the principles of commerce, must be far more useful than one who is satisfied to pick up merely the routine work of the office. A clerk who takes an approved course of study and attends classes regularly at a commercial institute becomes a more valuable and reliable member of the office staff: he improves his memory, gains initiative and takes a more intelligent interest in his work.

With regard to the Examinations of 1922, it will not perhaps be out of place to preface the report with a few words on their conduct in Ireland.

Ireland has for many years provided a fair proportion of the candidates, and it is greatly to her credit that this year the proportion has been well maintained. Especially is this true of Belfast. The conditions there during the period when the May-June Examinations were being held were at their very worst. Extracts from the reports of the Superintendents in Belfast show what had to be faced by the candidates in working their papers. One writes: "Everyone connected with these Examinations deserves a medal for pluck in attending. It was not easy to read Shorthand speed last night to the tune of rifle and machine gun fire. At one instant I thought we should have to give up the attempt to carry on." Another writes: "The dictation at this School was read under very trying conditions. When the reader com-

menced heavy firing started in a neighbouring street and the effect was evident on the students." And again: "The conditions were worse last night than ever. Some of those going to the School met in Royal Avenue wounded men carried out from the fighting line; and the Superintendents had to pass through such scenes to get to the School." All honour both to the candidates and superintendents who carried on the work in the midst of such difficulties and dangers!

The Examinations were held, as usual, at two periods, March-April and May-June. In March-April the number of entries was 22,160 and in May-June 38,172. The papers worked were divided between the two Examinations as follows:—

	March-April.	May-June.	Total.
Advanced Stage	2,371	6,052	8,423
Intermediate Stage	5,903	14,313	20,216
Elementary Stage	12,699	15,437	28,136

In addition to the 56,775 papers worked in the written examinations, 925 candidates presented themselves for the *viva voce* Examinations in Modern Languages.

The subjects of Examinations this year were:—

- Arithmetic.
- English.
- Book-keeping.
- Shorthand.
- Typewriting.
- Economic Geography.
- Economic History.
- Economic Theory.
- Précis-writing.
- Commercial Correspondence and Business Knowledge.
- Commercial Law.
- Company Law.
- Accounting.
- Banking.
- Theory and Practice of Commerce.
- Railway Law and Practice.
- Railway Economics.
- Shipping Law and Practice.
- History of Inland Transport.
- Insurance Law and Practice.
- French.
- German.
- Italian.

Spanish.
Russian.
Dutch.
Portuguese.
Swedish.

Arithmetic.—The total number of papers worked in all three Stages was 5,560, as compared with 4,387 in 1921. In Stage III. the number of papers worked was 204: 24 candidates obtained first-class certificates, 82 obtained second-class certificates, and 98 failed. The Examiner reports that while he received a few really excellent papers in this Stage, many candidates entered who were nowhere near the required standard, having, *e.g.*, no understanding of logarithms, nor training in mensuration.

In Stage II. there were 1,282 candidates, of whom 170 obtained first-class certificates, 611 obtained second-class certificates, and 501 failed. The failures were, of course, mainly due to incomplete preparation; but in some cases "howlers" could have been prevented by the exercise of a little intelligence. For instance, one candidate, informed that the population of New Zealand in 1911 was 1,008,468, and that the increase per 1,000 since then was 208, worked out the present population at more than 200,000,000,000!

In Stage I. there were 4,074 candidates, of whom 2,911 passed and 1,163 failed. The Mental Arithmetic is better than in 1921, while the work of Part II. is also satisfactory on the whole. Unfortunately, the Examiner has to complain, as usual, of the very bad style in which candidates from some centres are allowed to do their work. This is, of course, a familiar *cri de cœur* of examiners in every subject. If students and teachers could only realise how much good style counts in presenting an answer in an examination, they would surely devote more attention to this side of their work.

English.—The total number of papers worked in all three Stages was 3,790, as compared with 2,930 last year. The highest previous entry was 3,351 in 1920, when English was one of the subjects set for the special *Daily Sketch* prizes. It is satisfactory to note that the figure for this year is the highest on record, but in view of the importance of English as the bedrock of all our education, commercial or otherwise, one would like to see still further large increases in this subject.

In Stage III. the number of candidates

was 213, of whom 14 obtained first-class certificates, 109 obtained second-class certificates, and 90 failed. The corresponding figure for last year was 106, so that there has been an increase of 100 per cent. in this Stage. This in itself is satisfactory, but, unfortunately, there does not appear to have been any improvement in quality proportional to the increase in quantity. In spite of some excellent work the essays and the *précis*-writing were generally poor. For the first time in this Stage prescribed books were set, and the Examiner reports that as a rule the answers to the questions set on these gave most satisfaction.

In Stage II. there were 1,154 candidates, of whom 99 obtained first-class certificates, 693 obtained second-class certificates, and 362 failed. Here, again, prescribed books were set for the first time. The Examiner reports that, as a rule, the work on "The Idylls of the King" was good, while that on "Gulliver's Travels" was generally weak.

In Stage I. 2,423 papers were worked; 1,594 candidates passed and 829 failed. The Examiner reports some improvement in the analysis of sentences, although in certain centres the work on this question was deplorable. With regard to the essay writing, there seems to be a growing tendency among younger candidates to write irrelevantly and to enlarge upon points which have nothing whatever to do with the main issue. In certain groups the fault is so marked as to suggest that it is not discouraged by the teachers. Some of the answers to the "character" questions brought curious information: according to one writer, "Shylock is a famous detective (surname Holmes) and he appears in 'The Merchant of Venus';" while another described *Horatius* as "one of Mickawber's most famous poems."

Book-keeping.—This is still far and away the most popular of the subjects of examination. The number of papers worked in all three stages was 18,684, as compared with 17,300 in 1921. The subject coming nearest to it in popularity is Shorthand, in which the number of papers worked this year was 11,229.

In Stage III., 3,565 papers were worked. 410 candidates obtained first-class certificates, 1,804 obtained second-class certificates, and 1,351 failed. Some very good work was submitted in this Stage, but the Examiner draws attention to the fact that many candidates were without useful

knowledge of Cost Accounts—a subject of growing importance to-day.

In Stage II. 6,711 candidates presented themselves, of whom 888 obtained first-class certificates, 4,197 obtained second-class certificates, and 1,626 failed. The quality of the work shows a distinct improvement as compared with that of last year, although, unfortunately, according to the Examiner, "a large number of candidates appear incapable of expressing intelligently in words their knowledge with regard to the questions asked."

In Stage I., of 8,408 candidates, 5,187 passed and 3,221 failed. The attention of teachers should be drawn to the report of the Examiner: "It is noted with regret that a certain number of candidates, when dealing with purchases, sales and kindred items, still employ methods long fallen into disusage, and quite impracticable in modern commerce. Textbooks of authority do not advocate these methods: it can only be assumed, therefore, that some teachers have failed to keep in touch with modern practice."

Shorthand. The total number of papers worked this year was 11,229, an increase of 389 over the figure for 1921. In Stage III. there were 971 candidates, of whom 70 passed the 140 words per minute test, 490 passed the 120 words per minute test, and 411 failed. In Stage II. there were 5,184 candidates, of whom 1,572 passed the 100 words per minute test, 1,846 passed the 80 words per minute test, and 1,766 failed. In Stage I. tests at both 50 and 60 words per minute were introduced this year. 5,074 papers were worked. 2,325 candidates passed the 60 words per minute test; 1,626 passed the 50 words per minute test, and 1,123 failed.

The Examiner in his report quotes a large number of the mistakes made by candidates, which, as he takes care to point out, are by no means restricted to writers of Pitman's Shorthand. Among these may be mentioned "assured all over there are terms" for "shared by every other Railway Chairman"; "numbers and accounts" for "pros and cons"; "to prejudice a shareholder by seeming to turn a blind eye to facts" for "to preach a shallow optimism that turned a blind eye to facts"; "decreased gas in the price" for "prominence given in the press"; "take in February the fact" for "it never can be felt." In Stage I. "York" was

turned into "Hull," "Selkirk," "Sligo," "Wigan," and "Warwick"; "our complement of horses" into "our compliments to the horses." Outlines were often guessed at without the slightest consideration of the context. Geographical names and the headings of letters fared badly: thus the words "Stoke-on-Trent. 1st August, 1922," were turned into "Exchanged in transfer, justified in London, 1922," and "Stoke Newington, Distrain, First class, 1922."

Typewriting.—The total number of papers worked was 5,136, as compared with 4,503 in 1921. In Stage III. 507 scripts were submitted: 142 obtained first-class certificates, 235 obtained second-class certificates, and 130 failed. There would appear to be plenty of room for improvement in the methods of displaying the work, and in making effective use of varying line-spacing, width of margins and so forth; while many candidates failed altogether in the Time Test.

In Stage II. the papers worked were 1,767: 526 candidates obtained first-class certificates, 869 obtained second-class certificates, and 372 failed. The work in this Stage was on the whole better than in previous years, and, indeed, was more accurate and better displayed than much of that submitted in Stage III.

In Stage I. 2,862 papers were worked: 1,895 candidates passed, while 967 failed. Here, again, the Examiner complains of the lack of education and general intelligence shown by many of the candidates. Bad mis-spellings indicated unfitness for position as typists: the plural of *tableau* was given by one candidate as "tabloids"; of "man-of-war" as "sailor"; of "woman-servant" as "domestic servant"; one defined "a perfect erasure" as "a mistake that cannot be rubbed out"; while another wrote "there has been many decades during the past year."

Economic Geography.—285 papers were worked: in Stage III. four candidates obtained first-class certificates, 14 obtained second-class certificates, and 13 failed. Too many candidates are still careless or ignorant about such fundamental points as latitude and longitude, rainfall, the meaning of such terms as "natural region," and so forth. In Stage II. 9 candidates obtained first-class certificates, 63 obtained second-class certificates, and 31 failed. Apparently more attention than usual has been paid to the Examiner's reports with the result that the answers to the

compulsory part of the paper showed considerable improvement; but here again the ignorance as to the meaning of the term "natural region" was very general. The average of the work done was greatly reduced by the presence of a number of candidates who should have entered for the Elementary Stage. In Stage I. 100 candidates passed and 51 failed. Here, as indeed throughout the subject, the Examiner is of opinion that much of the teaching is bad, and is completely divorced from any intelligent study of the physical features. On the other hand there is wide evidence of "cramming" the commercial facts, and this leads to absurd errors which would not be made if the candidates had a glimmering of the reasons of the facts which they so ignorantly mis-state.

Economic History.—The number of papers worked was 53. In Stage III., of 21 candidates none obtained first-class certificates, 15 obtained second-class certificates, and 6 failed. The work was generally satisfactory, although none of striking quality was submitted. In Stage II. one candidate obtained a first-class certificate, 8 obtained second-class certificates, and 23 failed. Unfortunately, as was the case last year, most of the work in this Stage was very poor, and showed little or no real knowledge of history.

Economic Theory.—The number of papers worked was 259. In Stage III. 25 candidates obtained first-class certificates, 63 obtained second-class certificates, and 28 failed. The general character of the work was satisfactory, some of it of high quality, although, as usually happens, the Examination was attempted by a certain number who should have been content to enter in a lower Stage. In Stage II. 15 candidates obtained first-class certificates, 85 obtained second-class certificates, and 43 failed.

Précis-Writing.—The number of papers worked was 114. In Stage III. 25 candidates obtained first-class certificates, 63 obtained second-class certificates, and 28 failed. The worst fault was prolixity, and it was evident that many candidates had not practised the art of restricting themselves within a set limit of words. In some cases they exceeded the prescribed number, 300, by 500 words or more. The work in Stage II. (where 8 obtained first-class certificates, 37 obtained second-class certificates, and 11 failed) was decidedly better in this respect, and candidates

generally showed some power of epitomising the subject matter.

Commercial Correspondence and Business Knowledge.—The total number of papers worked was 3,935. In Stage III. 4 candidates obtained first-class certificates, 38 obtained second-class certificates, and 48 failed. In Stage II. 55 obtained first-class certificates, 762 obtained second-class certificates, and 306 failed. In Stage I. 1,796 passed and 926 failed. Almost all candidates were very weak in Commercial Correspondence. "It should be clearly realised," writes the Examiner, "that ability to express oneself clearly, in a manner calculated to convey the desired impression and leave no room for doubt, is an essential condition for success in this Examination."

Commercial Law.—520 papers were worked. In Stage III. 29 candidates obtained first-class certificates, 217 obtained second-class certificates, and 61 failed. But for the fact that a number of candidates took this Stage who should have entered for Stage II., the work here would have been extremely satisfactory. As the Examiner remarks in his report, no candidate should attempt this Examination unless he has studied the subject for at least two years or has previously obtained a pass in Stage II. Complaint is also made here, as indeed by most Examiners, of bad spelling, bad writing, bad composition and bad arrangement of the answers—faults which ought not to exist at this Stage. In Stage II. 49 obtained first-class certificates, 133 obtained second-class certificates, and 31 failed. While these figures indicate a good average of work, various extracts quoted from the answers in the Examiner's report show that he has only too much reason to complain of illiteracy on the part of various candidates.

Company Law.—344 papers were worked. In Stage III. 18 candidates obtained first-class certificates, 120 obtained second-class certificates, and 35 failed. The majority of the papers were carefully and intelligently written, and showed that the writers possessed a sound knowledge of the principles of the subject. In Stage II. 49 candidates obtained first-class certificates, 112 obtained second-class certificates, and only 10 failed. Here again it was clear that the great majority had a sound knowledge of the elementary principles of Company Law, though a good many showed an imperfect

acquaintance with the form and substance of a Memorandum of Association.

Accounting.—745 candidates sat for this examination, of whom 95 obtained first-class certificates, 386 obtained second-class certificates, and 264 failed. The work sent in was creditable, but a good many candidates showed weakness in answering Income Tax Questions.

Banking.—The number of papers worked was 66. Ten candidates obtained first-class certificates, 26 obtained second-class certificates, and 30 failed.

Theory and Practice of Commerce.—For the first time an Examination in Stage I. of this subject was introduced this year. The total number of papers worked in all three Stages was 570. In Stage III. 16 candidates obtained first-class certificates, 101 obtained second-class certificates, and 59 failed. In Stage II. 24 obtained first-class certificates, 205 obtained second-class certificates, and 83 failed. In Stage I. 16 passed, while 66 failed. The large percentage of failures in the last-named Stage is very noticeable: as the Syllabus covers a very limited field candidates are expected to show a reasonable knowledge of the subjects set. In all three Stages the Examiner thinks that better results would be obtained if teachers gave their students more frequent opportunities of expressing their ideas in writing.

Railway Law and Practice. 207 papers were worked in this subject. 50 candidates obtained first-class certificates, 110 obtained second-class certificates, and 47 failed. Here again the Examiner complains of the defective general education of many of the students, some of whom, he says, "ought to go back and take a course in English."

Railway Economics.—This subject was introduced into the Syllabus this year. 67 candidates presented themselves, of whom 15 obtained first-class certificates, 28 obtained second-class certificates, and 24 failed. Taken on the whole, the examinees were well prepared.

Shipping Law and Practice.—Only 22 candidates entered for this subject an unsatisfactory figure when the enormous size and importance of the shipping industry of this country is borne in mind. Five candidates obtained first-class certificates, 10 obtained second-class certificates, and 7 failed. Again the Examiner complains of the very poor standard of general educa-

tion possessed by the Candidates. "The spelling was lamentably weak, and this often went with a very limited power of expression. In fact, many of the candidates are sadly lacking in their knowledge of their mother-tongue. This was fatal to their rendering first-class answers to the questions set." It is deplorable that it should be necessary to write in this way of candidates in Stage III.

The History of Inland Transport, a new subject of examination this year, only attracted one Candidate, who was awarded a second-class certificate.

Insurance Law and Practice, also introduced this year, only attracted two candidates, of whom one obtained a second-class certificate, and the other failed.

MODERN LANGUAGES.

French. The total number of papers worked in this subject was 4,070, as compared with 3,697 in 1921. In Stage III. 67 candidates obtained first-class certificates, 326 obtained second-class certificates, and 256 failed. It is satisfactory to learn that "some quite delightful essays were written on the subject 'Les Châteaux en Espagne,'" but, on the other hand, a good many candidates exhibited an ignorance of grammar which is quite inexcusable in an advanced examination. In Stage II. 139 candidates obtained first-class certificates, 876 obtained second-class certificates, and 553 failed. Whilst a certain number of very good papers were worked, the Examiner reports again in many of the weaker students an ignorance of grammar which is almost staggering. Such forms as *je faisais*, *je marcha*, *vous connais* occurred in about fifty per cent. of the papers. It is to be feared that there is a very strong tendency to slipshod teaching which, while attempting to build up a showy superstructure leaves the foundations to take care of themselves. A thorough grasp of grammar is and must always remain the bedrock on which to raise a knowledge of any language, and teachers who imagine that they can dispense with this are laying up trouble for themselves and for their luckless pupils.

In Stage I. 1,309 candidates passed and 544 failed. The results here appear to have been generally satisfactory.

German still shows but little sign of recovering its pre-war popularity, when the number of papers worked was 826 (in 1914). Indeed, the figure this year, 276, shows a

falling off of 56 as compared with that of 1921. In Stage III. 12 candidates obtained first-class certificates, 36 obtained second-class certificates, and 8 failed. The work here was rather below the usual standard. In Stage II. 21 candidates obtained first-class certificates, 55 obtained second-class certificates, and 28 failed. While several of the papers were excellent, the general level was not high: there was much weakness in grammar, and much slipshod and untidy writing, both in English and German. In Stage I. 59 candidates passed and 57 failed. Here, unfortunately, the standard of work was (except in a few cases) very low. The failures, which were far too numerous, were due to gross carelessness and ignorance of grammar.

Italian.—In Stage III., of 20 candidates, 8 obtained first-class certificates, 7 obtained second-class certificates, and 5 failed. In Stage II. 9 obtained first-class certificates, 21 obtained second-class certificates, and one failed. In Stage I. 39 passed and 3 failed. The small proportion of failures in all Stages is satisfactory.

Spanish.—The number of entries in Spanish continues to increase steadily. This year 676 papers were worked, as compared with 633 in 1921. In Stage III. there were 131 candidates, of whom 17 obtained first-class certificates, 72 obtained second-class certificates, and 42 failed. Here, again, complaints are made of the students' ignorance of the grammar, but, on the other hand, the essays were, as a rule, satisfactory. In Stage II. 26 candidates obtained first-class certificates, 150 obtained second-class certificates, and 55 failed. The Examiner reports favourably on the general excellence of the work in this Stage, which shows a distinct improvement over that done in previous years. In Stage I. 264 candidates passed and 50 failed. The work on the whole was satisfactory, although there was room for considerable improvement in the knowledge of grammatical rules.

Russian.—In 1917, when high hopes were entertained of the assistance which Russia was going to give the Allies in the War, a remarkable impulse was given to the study of Russian in this country. As one result of this the number of entries at the Society's Examinations rose to 266. With the collapse of the Russian Empire this number fell rapidly, and this year the total number of papers worked was only 43. In Stage

III. 4 candidates obtained first-class certificates, 7 obtained second-class certificates, and 2 failed. The average quality of the work was rather poor, and students should realise that it is useless to attempt the examination in this Stage unless they possess a thorough knowledge of Russian grammar, idiom, and advanced syntax. In Stage II. 5 candidates obtained first-class certificates, 10 obtained second-class certificates, and a most satisfactory feature—there were no failures. In Stage I. 12 candidates passed and 3 failed. The work here reached a higher standard than last year, and there was a distinct improvement in the answers to the grammatical questions.

Dutch.—Only 7 papers were worked in this subject. In Stage III. one candidate obtained a second-class certificate and one failed. In Stage II. 2 candidates obtained second-class certificates and 3 failed. The work was of very poor quality in both Stages. The Examiner mentions that all candidates in Dutch seem to assume that the German and Dutch languages are practically identical, and that if they obtain a certificate in German, their success in Dutch will follow as a matter of course with very little additional study. This is a grave error.

Portuguese.—The number of papers worked in this subject was 13, the same number as last year. In Stage III. one candidate obtained a first-class certificate, 6 obtained second-class certificates, and one failed. In Stage II. one obtained a first-class certificate, 3 obtained second-class certificates, and one failed.

Swedish.—In Stage III. one candidate obtained a first-class certificate, one obtained a second-class certificate, and one failed. In Stage II. the results were very poor: one candidate obtained a first-class certificate and four failed.

COMMERCIAL KNOWLEDGE CERTIFICATES.

The increase, noted in last year's report, in the number of Candidates entered from Higher Elementary Schools, and also the new Central Day Schools set up under various Education Authorities, has been well maintained. Most of these Candidates take a group of subjects qualifying for the Certificate in Elementary Commercial Knowledge. To gain this special Certificate, Candidates must pass in Arithmetic, Book-keeping, English and one other subject within three consecutive years, but it is

satisfactory to find that many pupils from the Day Schools mentioned above, pass in the necessary subjects in one year. In view of the fact that a fairly high standard is maintained in the Elementary Stage (it is by no means a first year's examination) the results at Day Schools under the local Education Authorities mentioned, set forth in the following table give evidence of really excellent preparation.

a candidate is that he should be able to express himself correctly in his mother-tongue. The advice, which is obvious enough, ought to be quite unnecessary: unfortunately, it is not.

The second point is akin to the first. From all the Examiners in Modern Languages comes the same complaint: candidates do not know the grammar of the languages which they are supposed to have

	Elementary Stage, 1922.

Northampton, Town and County School	30	93	80
West Ham, Water Lane Higher Elementary School	26	164	146
Wood Green, Central County School	34	84	80
London, "Mary Datchelor" Girls' School	18	40	40

After a careful study of the Examiners' Reports, two principal facts emerge. Bitter complaint is made by nearly all the Examiners that in many cases the candidates' ignorance of their mother tongue is profound. A very large number of the failures in all subjects and in all Stages is due to this cause. Both teachers and students ought to realise that high marks cannot be given to a candidate whose spelling and grammar are very defective, and cannot be too strongly impressed upon them that they have to do with the training of the mind. As for these, or, indeed for any other, the first essential in

studied. To master the grammar of a language undoubtedly entails long hours of hard, uncompromising work; and it is to be feared there are many, both among teachers and students, who shirk what they can only make a dull and uninteresting task, and are content with a superficial and inaccurate acquaintance with a more or less extensive vocabulary. Such an acquaintance is of little or no value. No one has any really adequate knowledge of a language unless he is firmly grounded in the main principles of its grammar. This remark again is obvious and ought to be unnecessary. Again, unfortunately, it is not.

DETAILS OF THE 1922 EXAMINATIONS.

SUBJECTS.	STAGE III.—ADVANCED.				STAGE II.—INTERMEDIATE.				STAGE I.—ELEMENTARY.			Total number of Papers worked in all Stages.

DIAGRAM SHOWING PROGRESS OF EXAMINATIONS, 1900-1922.

The continuous line shows the number of candidates, the dotted line the number of papers worked.

The thanks of the Council are again accorded to the Court of the Clothworkers' Company, who have generously renewed their grant of £40, to be expended in providing medals in all the subjects of examination where the work of candidates attains a sufficiently high standard. There is no doubt that these medals are highly valued by those who win them, and they have done much to maintain or raise the level of excellence in the papers worked.

The Examination Syllabus for 1923* has been issued. In it will be found the fullest possible information about the examinations, a syllabus of each stage of each subject, and a list of centres. The papers set in April and May, 1922, have been reprinted in six pamphlets. Each pamphlet contains, in addition to the

papers of each stage, the syllabuses of the subjects in the pamphlet and the Examiners' reports on the papers worked. The attention of both teachers and students may be drawn once more not only to the syllabuses, but also to the remarks of the various examiners on the results of last year. It will be found that these contain many valuable and helpful suggestions, and the work of the candidates year after year shows that far too little attention is paid to them.

The regulations for the Oral Examinations in Modern Languages are also given at full length in the syllabus.

* The price of the Syllabus for 1923 is 4d., post free. Copies can be obtained on application to the Examinations Officer, Royal Society of Arts, Adelphi, London, W.C. (2). The price of the pamphlets containing the 1922 papers is 4d. each, post free. Particulars of these may be obtained as above.

NOTES ON BOOKS.

BUSINESS GEOGRAPHY. By Ellsworth Huntington and Frank E. Williams, with the co-operation of Robert M. Brown and Lenox E. Chase. New York: John Wiley and Sons, Inc., London: Chapman and Hall, Ltd. 13s. 6d. net.

Probably in no class of text books has there been more improvement during the last quarter of a century than in those which deal with geography, and some of the best of these come from America. A little while ago the writer of this note met a young Oxford geographer who was forsaking Isis for the Hudson River "because they take geography seriously in the States." This book, which is one of a series by Mr. Ellsworth Huntington, in collaboration with other writers, goes far to prove that the Oxonian was right. The modern conception of geography—at all events in America, though we hope not only there—is immense: it

embraces not merely physical and political features, but practically every aspect of human activity.

The present volume treats of the kind of geography that the business man needs. It deals in the first instance with principles, and the effects of specific geographic factors; it then passes on to types of business communities, the business of the continents, and the business of the United States. A student who has mastered the book will have a very good general knowledge of the various industries carried on in different parts of the world, and he will know why they have grown up in such and such parts rather than elsewhere. Nothing connected with human activity is alien to the modern geographer; thus, we have illustrations of Mexicans baking bread in a primitive mud oven, and of an Indian coolie lying on his back and working a punkah with his foot, and also particulars of the great "movie" industry: it

connection with which it is estimated that the picture theatres take well over a billion, and perhaps nearly a billion and a half dollars, a year.

An excellent feature of the book is the problems set at the end of each chapter, which should start the student thinking for himself. There are also a large number of tables specially calculated to give material for map making.

THE LIBRARY.

The following books have been presented to the Library since the last announcement. Except where otherwise stated, they have been presented by the publishers:—

- Anglo-Mexican Petroleum Co., Ltd. *Mex Fuel Oil*. Second Edition. London: George Philip & Son, Ltd., 1921.
- Beck, Ernest G. *Real Mathematics*. London: Henry Frowde & Hodder & Stoughton 1922.
- Bailby, Sir George, F.R.S.—*Aggregation & Flow of Solids*. London: Macmillan & Co., Ltd. 1921.
- Birck, Dr. L. V.—*The Theory of Marginal Value*. London: George Routledge & Sons, Ltd. 1922.
- Bisacre, F. F. P., O.B.E., M.A., B.Sc.—*Applied Calculus*. London: Blackie & Son, Ltd. 1921.
- Cain, John Cannell, D.Sc.—*The Manufacture of Dyes*. London: Macmillan & Co., Ltd. 1922.
- Chittick, James.—*Silk Manufacturing and its Problems*. New York 1913. Presented by the Author.
- Clapham, Charles B., B.Sc.—*Metric System for Engineers*. London: Chapman & Hall, Ltd. 1921.
- Cornford, L. Cope.—*The Designers of our Buildings*. London: Royal Institute of British Architects. 1921.
- Cross, Charles F. and Charles Dorée.—*Researches on Cellulose (1910-1921)*. London: Longmans Green & Co. 1922.
- Cundall, Frank, F.S.A.—*Handbook of Jamaica, 1922*. London: Edward Stanford. 1922.
- Dawson, Robert MacGregor, M.A., D.Sc.—*The Principle of Official Independence*. London: P. S. King and Son, Ltd. 1922.
- Deerr, Noël.—*Cane Sugar*. Second Edition. London: Norman Rodger, 1921.
- Dudgeon, Gerald C., C.B.E.—*The Agricultural & Forest Products of British West Africa*. Second Edition. London: John Murray. 1922.
- Evans, Edwin J.—*Building Contracts*. London: Chapman & Hall, Ltd. 1922.
- Fleming, A. P. M., C.B.E., M.Sc., and J. G. Pearson, B.Sc.—*Research in Industry*. London: Sir Isaac Pitman & Sons, Ltd. 1922.
- Grasser, Dr. Georg.—*Synthetic Tannins*. Translated by F. G. A. Enna. London: Crosby Lockwood & Son. 1922.
- Gregory, T. E. G., B.Sc.—*Tariffs: A Study in Method*. London: Charles Griffin & Co., Ltd. 1921.
- Hadfield, Sir Robert A., Bt., D.Sc., F.R.S.—*The Work and Position of the Metallurgical Chemist*. 1921.
- Hall, B. J.—*Blue Printing and Modern Plan Copying*. London: Sir Isaac Pitman & Sons, Ltd. 1921.
- Hewett, Arthur J.—*The Letter Cutter's Manual*. London: The Trade Papers' Publishing Co., Ltd. 1921.
- Hull, Thomas—*Oils, Fats and Fuels*. London: Blackie & Son, Ltd. 1921.
- Isaac, Charles Percival—*The Menace of Money Power*. London: Jonathan Cape. 1921. Presented by Mr A. Honeysett.
- Jeanes, Herbert—*The Periods in Interior Decoration*. London: The Trade Papers' Publishing Co., Ltd. 1921.
- Kaye, G. W. C., O.B.E., M.A., D.Sc.—*The Practical Applications of X-Rays*. London: Chapman & Hall, Ltd. 1922.
- Lethaby, W. R.—*Form in Civilization*. London: Oxford University Press. 1922.
- Loring, F. H.—*Atomic Theories*. London: Methuen & Co., Ltd. 1921.
- Macara, Sir Charles W., Bt.—*Recollections*. London: Cassell & Co., Ltd. 1921.
- Malinowski, Bronislaw, D.Sc., Ph.D.—*Argonauts of the Western Pacific*. London: George Routledge and Sons, Ltd. 1922.
- Matthis, Alfred R.—*Insulating Varnishes in Electrotechnics*. Manchester: John Heywood, Ltd. 1922. Presented by Messrs. Attwater & Sons, Preston.
- Millar, Andrew.—*Painting troubles and their Remedy*. London: The Trade Publishing Co., Ltd. 1921.
- Mitzakis, Marcel.—*The Oil Encyclopedia*. London: Chapman & Hall, Ltd. 1922.
- Palmer A. Risdon, B.Sc., B.A.—*Finance*. Two vols. London: G. Bell & Sons, Ltd. 1922.
- Parr, G. D. Aspinall, M.Sc.—*Electrical Engineering Testing*. Fourth Edition. London: Chapman & Hall, Ltd. 1922.
- Pennell, Joseph.—*The Graphic Arts*. Chicago: University Press.
- Penzer, N. M., M.A.—*The Mineral Resources of Burma*. London: George Routledge & Sons, Ltd. 1922.
- Redwood, Sir Boverton, Bart., D.Sc.—*A Treatise on Petroleum*. Fourth Edition. Three Vols. London: Charles Griffin & Co., Ltd. 1922.
- Rowntree, H. Seebohm.—*The Human Factor in Business*. London: Longmans, Green & Co. 1921.
- Russell, Edward J., D.Sc., F.R.S.—*Soil Conditions and Plant Growth*. Fourth Edition. London: Longmans, Green & Co. 1921.
- Schlich, Sir William, K.C.I.E., F.R.S.—*Schlich's Manual of Forestry*. Vol. 1. Fourth Edition. London: Bradbury, Agnew & Co., Ltd. 1922.

Stevens, Alexander, M.A., B.Sc. — Applied Geography. London : Blackie & Son, Ltd. 1921.

Verstone, P. E. — The Manufacture of Paper Containers. London : Verstone & Co. 1922.

Woodhouse, Thomas. — 1. The Handicraft Art of Weaving. 2. Yarn Counts and Calculations. London : Henry Frowde & Hodder & Stoughton. 1921.

Young, Sydney, M.A., D.Sc., F.R.S. — Distillation Principles and Processes. London : Macmillan & Co., Ltd. 1922.

MEETINGS OF THE SOCIETY.

ORDINARY MEETINGS.

Wednesday evenings, at 8 o'clock (unless otherwise announced) :—

NOVEMBER 13 (Monday).—JOHN SLATER, F.R.I.B.A., Member of the Council of the Society, "The Strand and the Adelphi : their Early History and Development." Lord ASKWITH, K.C.B., K.C., D.C.L., Chairman of the Council and a Vice-President of the Society, will preside. (The Paper will be fully illustrated with lantern slides.)

NOVEMBER 15. — Overingenieur DR. SIGURD SMITH (Charlottenlund, Denmark), "The Action of the Beater in Paper Making, with special reference to the Theory of the Fibre Board and its application to Old and New Problems of Beater Design." CAPTAIN W. E. NUTTALL, M.B.E., Chairman of the Technical Section, Papermakers' Association, will preside. (Lantern illustrations.)

NOVEMBER 22.—BAILIE WILLIAM SMITH (Glasgow), Member of the Departmental Committee on Smoke Abatement, "The Economy of Smoke Abatement." THE RIGHT HON. LORD NEWTON will preside.

NOVEMBER 29.—MAJOR W. S. TUCKER, R.E., D.Sc., "The Hot Wire Microphone and its Applications." Admiral of the Fleet SIR HENRY B. JACKSON, G.C.B., K.C.V.O., D.Sc., F.R.S., will preside.

DECEMBER 6.—H. EMORY CHUBB, "Recent Developments in the Manufacture of Safes and Strong Rooms." (With Cinematograph illustrations.) LAURENCE CURRIE will preside.

DECEMBER 13.—SIR SIDNEY F. HARMER, K.B.E., Sc.D., F.R.S., Director of the British Museum of Natural History, "The Fading of Museum Specimens." THE EARL OF CRAWFORD AND BALCARRES, K.T., P.C., F.S.A., will preside.

INDIAN SECTION.

Friday afternoons, at 4.30 o'clock.

NOVEMBER 17.—J. W. MEARES, C.I.E., M.Inst.C.E., M.I.E.E., Member of the Institution of Engineers (India), "The Development of Water Power in India." SIR THOMAS H. HOLLAND, K.C.S.I., K.C.I.E., LL.D., D.Sc., F.R.S., Rector of the Imperial College of Science and Technology, will preside.

DECEMBER 15.—Commissioner F. de L. BOOTH TUCKER, "The Settlements of Criminal Tribes in India." SIR EDWARD R. HENRY, Bt., G.C.V.O., K.C.B., Inspector-General of Police, Bengal, 1891 : Commissioner of Police in the Metropolis, 1903-18, will preside.

DOMINIONS AND COLONIES SECTION.

Tuesday afternoon, at 4.30 o'clock.

DECEMBER 5.—MAJOR OWEN RUTTER, F.R.G.S., F.R.A.I., "North Borneo" (with Cinematograph Views).

PAPERS TO BE READ AFTER CHRISTMAS.

THOMAS H. FAIRBROTHER, M.Sc., F.I.C., and ARNOLD RENSHAW, M.D., D.P.H., "The relation between Chemical Constitution and Antiseptic Action in the Coal Tar Dyes."

CHARLES R. DARLING, A.R.C.Sc.I., "Electrical Resistance Furnaces and their Uses."

WILLIAM ARTHUR BONE, D.Sc., Ph.D., F.R.S., Professor of Chemical Technology, Imperial College of Science and Technology, South Kensington, "Recent Developments in Surface Combustion."

W. J. REES, Lecturer on Refractories in the University of Sheffield, "Progress in the Manufacture of Refractories."

ARTHUR W. REEVES, M.I.Mech.E., M.Inst. Auto. Eng., "Motor Railway Coaches."

MAURICE DRAKE, "The Development of Mediæval Technique in Stained Glass Windows."

EDWARD PARNELL, "The Resources and Trade of Sarawak."

C. AINSWORTH MITCHELL, M.A., F.I.C., "Handwriting and its value as Evidence."

PROFESSOR W. E. S. TURNER, D.Sc., Head of Department of Glass Technology, The University, Sheffield, "Heat Resisting Glasses."

THE EARL OF RONALDSHAY, G.C.I.E., late Governor of Bengal, "A Clash of Ideals as a Cause of Indian Unrest."

J. T. MARTEN, I.C., M.A., Imperial Census Commissioner in India, "The Indian Census, 1921."

SIR RICHARD A. S. REDMAYNE, K.C.B., M.Sc., M.Inst.C.E., M.I.M.E., F.G.S., The Base Metal Resources of the British Empire."

L. GUY RADCLIFFE, M.Sc. (Tech.), F.I.C., "The Essential Oils of the British Empire."

BRIGADIER-GENERAL H. A. YOUNG, C.I.E., C.B.E., "The Indian Ordnance Factories."

R. W. CHURCH, B.Sc., F.G.S., "Electrification of Indian Coalfields."

LIEUT.-COLONEL SIR LEONARD ROGERS, C.I.E., F.R.S., F.R.C.P., F.R.C.S., Physician and Lecturer, London School of Tropical Medicine, "Recent Advances towards the Solution of the Leprosy Problem."

INDIAN SECTION.

Friday afternoons, at 4.30 o'clock.

January 10, February 16, March 16
April 20, May 11.

DOMINIONS AND COLONIES SECTION.

Tuesday afternoons, at 4.30 o'clock

February 6, March 6, May 1.

CANTOR LECTURES.

Monday evenings, at 8 o'clock.

WILLIAM ARTHUR BONE, D.Sc., Ph.D., F.R.S., Professor of Chemical Technology, Imperial College of Science and Technology, South Kensington, "Brown Coal and Lignites." Three Lectures. November 27, December 4 and 11.

HENRY P. STEVENS, M.A., Ph.D., F.I.C., "The Vulcanisation of Rubber." Three Lectures. February 12, 19.

J. E. SEARS, C.B.E., M.A., M.I.Mech.E., Superintendent of Metrology, National Physical Laboratory, and Deputy Warden of the Standards, "Length Measurement." Three Lectures. March 5, 12, 19.

SAMUEL A. DAVIES, Chemical Department, Messrs. Rowntree & Co., York, "Cocoa and Chocolate." Three lectures. April 9, 16, 23.

MEETINGS OF OTHER SOCIETIES FOR THE ENSUING WEEK.

MONDAY, NOVEMBER 13.. Geographical Society, 135, New Bond Street, W., 8.30 p.m. Commander Frank Wild, "The Work of the Quest." Surveyor's Institution, 12, Great George Street, S.W., 8 p.m. Address by the President, Mr. J. M. Clark.

TUESDAY, NOVEMBER 14.. Illuminating Engineering Society, at the ROYAL SOCIETY OF ARTS, John Street, Adelphi, W.C., 8 p.m. Reports on progress during the vacation and Developments in Lamps and Lighting appliances

Petroleum Technologists, Institution of, at the ROYAL SOCIETY OF ARTS, John Street, Adelphi, W.C., 5.30 p.m. Mr. A. Millar, "The Galician-Canadian Pole Tool Drilling System."

Oriental Studies, School of, Finsbury Circus, E.C. Dr. T. G. Bailey, "The Sansas or Thieves of India: their Languages, History and Customs."

Metals Institute of (Scottish Section), 38, Elmbank Crescent, Glasgow, 7.30. Mr. J. W. Donaldson, "Non-Ferrous Alloys and their Uses in Marine Engineering and Shipbuilding."

Chadwick Public Lectures, at the Royal Sanitary Institute, 90, Buckingham Palace Road, S.W., 5.15 p.m. Miss A. D. Muncester, "Some Hygienic Aspects of Food and Food Preparation."

WEDNESDAY, NOVEMBER 15.. University of London, South Kensington, S.W., 5 p.m. Sir Frederick Bridge, "Some Operative Studies" Lecture I. "Euridice," by Peri (the first Opera, 1600).

Microscopical Society, 20, Hanover Square, W. 1. Mr. C. Beck, "Glare and Flooding in Microscope Illumination." 2. Dr. C. Singer, "The First Mechanical Microtome." 3. Prof. G. S. Thapar, "The Occurrence and Significance of a Third Contractile Vacuole in *Paramecium caudatum*." 4. Prof. B. L. Bhatia, "On the Significance of Extra Contractile Vacuoles in *Paramecium caudatum*."

Industrial League and Council, Caxton Hall, Westminster, S.W., 7.30 p.m. Sir Arthur R. Holbrook, "Industrial Liberty."

Public Health, Royal Institute of, 37, Russell Square, W.C., 4 p.m. Dr. G. E. C. Pritchard, "The Scientific Principles underlying Infant Feeding."

University of London, University College, W.C. 6.15 p.m. Mr. A. W. Flux, "Foreign Exchanges - the Relation of Prices in different Countries. Facts and Theories. (Lecture II.)"

THURSDAY, NOVEMBER 16.. Aeronautical Society, at the ROYAL SOCIETY OF ARTS, John Street, Adelphi, W.C., 5.30 p.m. Mr. R. M. Wood, "The Co-relation of Model and Full Scale Work."

Royal Society, Burlington House, Piccadilly, W., 4 p.m.

Child Study Society, 90, Buckingham Palace Road, S.W., 6 p.m. Mr. A. D'Arcy Chapman, "The Measurement of the Intelligence of School Children in Massachusetts, U.S.A."

British Decorators, Incorporated Institute of, Painters' Hall, Little Trinity Lane, E.C., 7.30 p.m. Mr. T. P. Bennett, "Wood-Work."

Literature, Royal Society of, 2, Bloomsbury Square, W.C., 5.15 p.m. Prof. J. Drinkwater, "Some Contemporary Poets."

Mechanical Engineers, Institution of (Midland Branch), The University, Edmund Street, Birmingham, 7.30 p.m. Mr. J. Fearn, "The Economics of Plant Purchase." (North-Western Branch), Memorial Hall, Albert Square, Manchester, 7 p.m. Mr. H. Wilkinson, "Cotton Opening, Mixing and Carding Machinery."

Electrical Engineers, Institution of, Savoy Place, Victoria Embankment, W.C., 6 p.m. Prof. M. Walker, "The Improvement of Power Factors" by the late Dr. G. Kapp.

Camera Club, 17, John Street, Adelphi, W.C., 8.15 p.m. Mr. T. H. B. Sharp, "Louds."

Linnean Society, Burlington House, Piccadilly, W., 5 p.m.

Chemical Society, Burlington House, Piccadilly, W., 8 p.m.

FRIDAY, NOVEMBER 17.. University of London, Zoological Theatre, University College, W.C., 5.15 p.m. Mr. C. T. Regan, "Problems of Evolution, with special reference to Fishes." (Lecture II.)

Mechanical Engineers, Institution of, Storey's Gate, Westminster, S.W., 6 p.m. Adjourned Discussion on "Electric Locomotives," by Sir Vincent L. Raven."

Journal of the Royal Society of Arts.

No. 3,652.

VOL. LXX.

FRIDAY, NOVEMBER 17, 1922.

All communications for the Society should be addressed to the Secretary, John Street, Adelphi, W.C. (2)

FUND FOR PURCHASING AND RENOVATING THE SOCIETY'S HOUSE.

SIXTH LIST.*

	£	s.	d.
Amount previously acknowledged	42,573	15	4
The South Metropolitan Gas Company	105	0	0
The Skinners' Company ..	26	5	0
The late Sir Richard Vassar-Smith, Bt., D.L. ..	21	0	0
Alexander Bremner, Esq. ..	20	0	0
Nathaniel Geach Burch, Esq. ..	10	10	0
Henry A. Haviland, Esq., M.B.	10	10	0
Sir R. N. Mookerjee, K.C.I.E. ..	10	0	0
Capt. James Charles Richards ..	10	0	0
K. Sumitomo, Esq. ..	10	0	0
John Hughes, Esq. ..	5	5	0
Louis Benjamin Tait, Esq. ..	5	5	0
Colonel Herbert A. Foster ..	5	0	0
Lieut.-Colonel Christian B. Hunter	5	0	0
J. Henry Monk, Esq. ..	5	0	0
George Harvey Whymark, Esq.	3	3	0
John Francis Costello, Esq. ..	2	2	0
Colonel Nicholas T. Belaiew, C.B.	1	1	0
George Halford, Esq., A.R.C.A.	1	1	0
James Robert Kirk, Esq., M.B.E.	1	1	0
	£42,830	18	4

The above list includes all subscriptions received up to November 14th. Further lists will be published in the *Journal* from time to time.

Fellows of the Society are reminded that the amount aimed at by the Council is £50,000, which will cover the cost of renovating and decorating the House.

* The five former lists were published in the *Journals* of December 2nd, 1921, January 18th, February 24th, May 5th and July 14th, 1922.

NOTICES.

NEXT WEEK.

WEDNESDAY, NOVEMBER 22nd, at 8 p.m.
(Ordinary Meeting.) BAILIE WILLIAM SMITH (Glasgow), Member of the Departmental Committee on Smoke Abatement, "The Economy of Smoke Abatement." THE RIGHT HON. LORD NEWTON, P.C., D.L., will preside.

FIRST ORDINARY MEETING.

WEDNESDAY, NOVEMBER 8th, 1922; LORD ASKWITH, K.C.B., D.C.L., K.C., Chairman of the Council, in the Chair.

The following candidates were proposed for election as Fellows of the Society:—

Allbright, William James, London.
Allan, James Boyd, Motherwell.
Ashford, Colonel Bailey K., M.D., D.Sc., C.M.G., San Juan, Porto Rico.
Atal, Brijmohan Lal, F.C.I., Chaura Rasta, Jaipur State, Rajputana, India.
Bailey, Thaddeus F., Alliance, Ohio, U.S.A.
Baker, Webster E. Byron, York, Penna., U.S.A.
Barton, P. A., Bangalore, India.
Bhargava, Rai Sahib Trilok Nath, B.A., Lucknow, India.
Bull, Alec G., Sutton, Surrey.
Cann, Edmund Henry Hope, Salkhia, India.
Cantell, Mark Taylor, M.Am.Soc.M.E., Winnipeg, Manitoba, Canada.
Chand, Hari, A.M.I.E.E., Sitapur, U.P., India.
Chatterjee, Nirmal Chandra, Dibrugarh, Assam, India.
Chubb, Harry Emory, Chorley Wood, Herts.
Dailey, Miss Dew, M.A., Parkersburg, Iowa, U.S.A.
Deacon, Henry, Blackpool, Lancashire.
Dean, Clayton Dewitt, Toronto, Ontario, Canada.
Dutt, L. B., Calcutta, India.
Edmiston, James E., Rancagua, Chili, S. America.
Egidius, Thorvald Fredrik, D.Sc., Utrecht, Holland.
England, Jack Culley, Purley, Surrey.
Eppel, B., Edinburgh.
Farley, Professor John Herbert, Appleton, Wisconsin, U.S.A.

- Feist, Henry James Banos, Leigh-on-Sea, Essex.
 Flower, Frederick William, A.S.A.A., London.

ADMISSION TO MEETINGS.

Fellows have the right of attending the Meetings and Lectures. They require no tickets, but are admitted on signing their names. Every Fellow can admit two friends to the Ordinary and Sectional Meetings, and to the Cantor and other Lectures. Books of tickets for the purpose are supplied on application to the Secretary of the Society, but admission can also be obtained on the personal introduction of a Fellow. For the Juvenile Lectures special tickets are issued.

A SUCCESSFUL CRUSADE AGAINST FLIES AND CHILD MORTALITY.

BY E. HALFORD ROSS,

A Senior Medical Assessor at the Ministry of Pensions; Medical Officer to the Factories of the City of London under the Home Office; Medical Member of Council, Industrial Welfare Society. Lately of the Public Health Department, County of London; Research Scholar at the Lister Institute and at the Liverpool School of Tropical Medicine. One time Health Officer of the Suez Canal and Cairo. Medallist, Royal Society of Arts.

The aim of medical research is the prevention of disease. To obtain even a reduction of a disease investigated within a life-time, in a large community, is rare. Yet the reduction of one house-fly borne disease has occurred in England and Wales within a decade; and a generation should see its prevention. The story is an interesting one.

A century ago several doctors suggested that maladies might be carried from one human being to another by mosquitoes; but they produced no definite evidence. In 1878, Bancroft, Cobbold and Manson declared that human blood worms were mosquito-conveyed. It was after Manson's careful work on this subject that he produced his famous induction that such insects were the vectors of malaria—a theory which was proved a fact by my brother, Sir Ronald Ross, in India in 1897-9. I visited him there then, and saw the development of disease parasites within the bodies of mosquitoes.

In 1900, the Suez Canal Company began an experiment at Ismailia, a small town in the Canal zone, with the object of preventing malaria. By means of draining

or oiling all stagnant water, mosquitoes were prevented from breeding, and by 1903 malaria was abolished and Ismailia made healthy. This successful experiment became famous, and it led to the ultimate cleaning of the Panama Canal zone as well, by the late General Gorgas in the early years of this century. In 1905, while a surgeon in the Royal Navy, I was appointed by the Egyptian Government to undertake similar measures at Port Said, and was for four years health officer there. The experiment at Ismailia was copied, Port Said was soon rid of its insect pest, and the death rate fell from 29 per 1,000 to 20 per 1,000. The town was converted from a "sink of iniquity" to a seaside health resort, and during the late war was used as a base for our troops and a position chosen for several general hospitals. The methods employed were imitated afterwards by Lord Allenby in his advance up the fever stricken Jordan valley, as described by him at the Mansion House in 1920. It was during that period at Port Said that the possibility of house-fly reduction, similar to the mosquito reduction then in progress, came under investigation. As mosquitoes disappeared, flies became more obvious. But little certain information was ready to hand concerning their breeding places and still less about their disease bearing propensities. In order to get rid of mosquitoes the local press in Egypt had been asked to help and had responded eagerly. But in the absence of knowledge regarding flies, one hesitated to ask again for a campaign against what is now known to be a source of high infant mortality.

In 1909, however, after transfer to Cairo an experience occurred which set aside all doubts as to the danger of house-flies. It was described by Sir John Bland-Sutton, at a meeting of the British Medical Association. "Dr Ross tells us that the spring of that year was ushered in by a heat-wave on May 1st, and the temperature rose to 102°F. in the shade. Fourteen days later the greatest plague of flies ever remembered appeared in the city. Food, milk and fruit were contaminated by them. In two months 3,000 children under five years of age succumbed to enteritis—a disease due to infection. It is not an unreasonable assumption that the death of the Egyptian infants, which induced Pharaoh to let the children of Israel go, was due to an epidemic of enteritis spread by an enormous swarm

of "divers sorts of flies." Cairo was a filthy town, in a grossly insanitary condition. The flies bred in myriads and the houses were soon swarming with the pest. The insect plague surpassed that of South Africa during the Boer War. It was followed rapidly by the death of the newly born, not merely that of the first born, as in the Biblical story. On all sides were the cries of Rachel weeping. The general death rate leapt up, and in one week it reached the appalling figure of 105 per 1,000. The hospitals, dispensaries, charities were worked at full pressure, but still the infants died. It was an experience never to be forgotten.

On returning to England in 1911, enquiry and research into flies and disease was begun first at the Liverpool School of Tropical Medicine, then at the Lister Institute of Preventive Medicine in London. At the former, the work of Howard, Hewitt, Nuttall, Austen, Graham-Smith, Tsuzaki, Ficker, Hamilton and Newstead was studied; these writers had shewn that flies breed in horse-manure and in stable and house-refuse. At the latter the then recent researches of Morgan and Ledingham had appeared; they had discovered a bacillus named *Morgan I.* in infants suffering from enteritis; had inoculated this bacillus into monkeys and produced a similar disease in them; and had found the same bacillus in and on flies caught in the houses of the infected children. No further proof of the implication of flies as transmitters of infantile enteritis was required. Koch's well-known postulates had been fulfilled, and the information wanting in Egypt was complete. It remained to apply the knowledge gained in order to reduce flies at home, to attack their breeding-places as those of mosquitoes had been attacked on the Suez Canal zone; and so reduce and perhaps prevent ultimately the fly-borne infant mortality. As at Port Said, an appeal was made to the Press.

The spring and summer of 1911 in England were unusually warm. May was fine and sunny, June was hot, July continued so. During the last week in July infants began to die of enteritis. Their death-rate rose from 173 to 304 per 1,000; a month later it had risen to 636 per 1,000. An article was written and published in *The Morning Post* on September 2nd entitled "Flies and the death of the Innocents," it pointed out that high

temperatures cause fly-eggs to mature rapidly, and heat quickens the development of fly-grubs; whilst rain drowns many grubs feeding in exposed places. It was shewn that the heat wave and drought conspire together to produce house-flies, and house-flies kill children. And it was suggested that these insects should be attacked while in the larval, grub, or crawling stage by cleaning manure-heaps, stables, ash-bins, collections of refuse, and the regular clearing of anywhere and everywhere where flies could breed. It was emphasised that this should be done periodically throughout the country as it had been done in the Canal zones with the breeding-places of mosquitoes. "Let it be remembered that house-flies are a sign of insanitation and their numbers a measure of that insanitation." The matter was taken up by Mr. T. P. O'Connor, who demanded that "the eyes of the general public should be opened to what was really a grave danger at present fully unrealised." Among others he quoted a paragraph which has proved a prophecy: "There is, however, already an improvement. Flies are not nearly so numerous as formerly in London. This is due partly to sanitary science, but partly to petrol. The mews in the west end have become garages, and the cab-horse and hack are disappearing. Their 'bedding' is no longer there to harbour and feed fly-grubs; and in the better residential neighbourhoods only one fly pesterer where before were dozens." Dr. Chalmers Mitchell, reviewing the work done at Port Said, in a middle article of *The Saturday Review*, said: "The diseases of the tropics make a dramatic appeal to us, and we are disposed to regard the familiar scourges of our own country as inevitable. But the extermination of the insect pests of our own houses is as important and as practicable as the campaign against mosquitoes and would lower the death-rate and increase the comfort and happiness of the population." It was little guessed then that ten years would turn the idea into an accomplished fact. Yet such is the case.

The following summer was wet and cold. Flies appeared in comparatively few numbers. But in the early spring of 1913, the suggestion was taken up again. Mr. Murray had prepared and published two books on the subject; Mr. Heinemann another. A review in *The Times Literary Supplement* was followed

by a leading article in the main issue. The prevention of house-flies rather than killing them was the main argument. *The Globe*, *Scotsman*, *Empire*, *Review* continued it. *The Daily Express* repeated it with headlines. Then came *The Graphic* and *Daily Graphic*, with pictures of fly-grubs and chrysalides; *The Daily News*, *The Liverpool Post*, *Cardiff Mail*, *Liverpool Echo*, *Sheffield Telegraph*, *Manchester Courier*, *Birmingham Daily Post*, *The Field*, *Country Life*, the late Mr. G. R. Sims in *The Referee*, and *Punch* repeated the suggestion. *The Daily Mail* started an annual campaign.

Early in 1914, information came from New York of an experiment conducted in the borough of Bronx. A chosen district containing 1,725 individuals and 302 children under five years of age, was protected against house-flies by an organisation in which Boy Scouts and Inspectors were employed to deal with fly-grubs in the courtyards, waste-spaces, and stables. Another similar area was allowed to pursue its usual fly-plagued course. As a result there were only 110 cases of infant sickness recorded in the protected area, while among the "outside" families there was a total of 165 cases. This was the first practical attempt to prevent fly-borne disease, and so far as it went, was successful. Then the story of "House Flies and disease" was told before the Royal Society of Arts on March 18th, 1914, when a lively discussion followed. Mr. Carmichael Thomas was present, and he invited Mr. Harold Cox and the Press Association to take up the crusade again. It was in consequence of this that fly-reduction was converted into a propaganda, in which almost every newspaper in the country played a part. The effect was immediate. On April 6th, 123 medical officers of health memorialised the Local Government Board (Ministry of Health). They appealed to householders to co-operate with the health authorities in the effort to get rid of all breeding-places for flies, of all collections of refuse and garbage. It was published broadcast with numerous letters and interviews. On May 24th, a *cause célèbre*, which produced considerable stir, began in the Law Courts. Mr. J. O. P. Bland sued a neighbour at Sunbury for stacking manure in an adjoining garden, thus producing flies. Mr. Terrall, K.C., and Mr. Clauson, K.C., cross-examined experts for three days; and in his judgment for the plaintiff, Lord Justice Warrington

decided that collections of horse-manure are sites of election for flies to breed, and as such are a public nuisance; he gave an injunction against the defendant. The case was reported widely, flies were denounced at the British Medical Association General Meeting at Aberdeen. The Local Government Board issued circulars, fly-prevention began to be taught in the schools. Infant Welfare Clinics paid special attention to fly-diseases; mothers were instructed to avoid fly-contamination of infants' food; posters and leaflets were distributed; the insects were filmed; and, finally, as such propaganda seems incomplete without its comic song, there appeared at the Vaudeville Theatre, "Where do the flies go in the winter time?" On several occasions various discussions arose concerning flies in which Mr. Gahan, of the British Museum (Natural History), the Vice-Chancellor of Cambridge, and Professor Howlett, of the Imperial College of Science, Lefroy of the Zoological Society, and others took part; these served to keep the subject constantly before the public.

There is no known method of accurately counting flying insects in any large locality; this was found a great difficulty in the areas of obvious mosquito and fever reduction; it is consequently quite impossible to measure the total number of flies in a whole country. But the numbers of horses, which are a chief source of flies, can be gauged; and the annual immigration of those birds which find in flies their prey, can be watched. Thus fly-reduction can be roughly estimated. In most of our towns, the cab-horse, bus-horse, tram-horse and riding-hack have gone, and they have taken their flies with them. Stables have been turned into garages, loose-box, "livery and bait" have disappeared, and the sites of election have become comparatively negligible in numbers. In the country the tractor is more slowly replacing the farm-horse, the delivery van is ousting the tradesman's cart. The Ministry of Agriculture states that there has been a reduction of 50,000 horses in agricultural holdings since 1911. And in allotments, gardens, farms and backyards, this propaganda has borne great fruit, for now only an occasional fly is seen where they before were swarming. This is confirmed by the decrease of swifts, swallows, and house-martins as noticed by "Bird Lover," Mr. Masfield, of Stafford, and A. C— B—, well-known naturalists.

The results of fly-reduction are most interesting. The Registrar General has very kindly supplied the following figures :—

ENGLAND AND WALES.

Deaths from enteritis among children under 5 years of age—

1901	1902	1903	1904	1905
35,103	16,656	21,582	33,922	24,040
1906	1907	1908	1909	1910
34,572	14,097	23,508	14,336	14,884

INTERNATIONAL LIST. A. B. C. D. E. F.

1911	1912	1913	1914	1915
40,470	8,478	22,431	19,500	16,310
1916	1917	1918	1919	1920
10,998	9,323	8,474	7,585	8,895

The year 1921 will be remembered as a record summer for warmth, drought and sunshine—ideal conditions for breeding flies ; but the fly resurtection proved abortive, and 14,195 deaths occurred—one-third that of the former warm year of 1911.

Flies are greatly reduced in numbers throughout the country. During this past summer of 1922, I have toured England and Wales looking for house-flies, as I used to look for mosquitoes at Port Said. In those places where formerly they bred in myriads, there are only a few. In other places, where before there were thousands, they are conspicuous by their absence. Out of the way villages, and some farm houses still shelter the grubs and insects, but such places are comparatively few and far between. There is no doubt of fly-reduction. And in this summer, the figures shewing our infant mortality reduction are astonishing. The number of total deaths is not yet available, but the accurately estimated death rate is available and stands, during the warmest weeks, at 50 per 1,000. Compared with that of 636 per 1,000 during the warm weeks of 1911, it is an amazing record. It is reflected in the general death rate. This has fallen to its lowest—8.9 per 1,000. Compared with that of 105 per 1,000 at Cairo during the epidemic of infantile enteritis in 1910, it is a practical testimonial unsurpassed for our powers of propaganda in an educated people.

Dr. Hamer, Health Officer to the County of London, in his recent report, ascribes fly-reduction to the advance of motor traffic. He is right ; but his explanation is not the complete one. The deaths in 1920 were 8,895 ; in 1921 they numbered

14,195 ; yet there was more motor traffic in 1921 than in 1920, as the registration returns show. The medical correspondent of *The Times* ascribes fly reduction to the weather. He is right ; but his explanation is not the complete one. The deaths in 1911 were 40,470 ; in 1921 they numbered 14,195 ; yet 1921 was a warmer, dryer, year. It is education, cleanliness, health, sanitation, propaganda, knowledge disseminated, science presented which has made the difference. Once more, though rarely, medical research has gained its aim. A disease investigated has been reduced in a large community within a decade. A life-time has seen it well started. A generation should see it prevented, and the life-waste of a great war replaced.

There are still deaths caused by flies among English children every year.

OBITUARY.

ARTHUR H. REID, F.R.I.B.A.—Mr. Arthur H. Reid died at Cape Town on October 18th. He went to South Africa in 1877 and was for a time in the municipal service there as a draughtsman and surveyor. Later on he became city engineer at Graham's Town, but retired from the public service in 1882. From then until 1887 he practised privately at Port Elizabeth, after which he left for the Rand goldfields, then recently discovered, where he was the first practising architect. Subsequently he returned to Cape Town, and practised in association with Mr. W. J. Delbridge.

Mr. Reid held a number of public offices : he was a member of the Cape Town City Council, and of the old Staats Raad of Johannesburg.

He was deeply interested in public health matters, and was instrumental in the training of Municipal inspectors for taking their diplomas in sanitary science. He was for a time President of the Association for the Prevention of Consumption and also President of the Cape Institute of Architects, and of the South African Institute of Real Estate valuers.

He joined the Society in 1899, was for some time a member of the Colonial Section Committee and he spoke in the discussion on Mr. Richard Jebb's valuable paper, "Imperial Problems of Asiatic Immigration," read on April 7th, 1908.

NOTES ON BOOKS.

THE PRACTICAL APPLICATION OF X-RAYS. By G. W. C. Kaye, O.B.E., M.A., D.Sc., A.R.C.Sc., F.Inst.P. London : Chapman & Hall, Ltd. 10s. 6d. net.

This volume is based to a large extent on the admirable course of Cantor Lectures delivered before the Society by the author in 1921.

The introductory chapter deals with the nature of X-rays, their generation, and the methods of detecting them. This is followed by chapters on the X-ray bulb, the high potential generator, and the measurement of X-rays. Chapter V. describes the medical applications of X-rays. This is a subject with which most readers will have some familiarity, although they may not know to what an extent the rays are now used, not only in ordinary medicine, but also in veterinary science; the author shows, for instance, a photograph of the X-raying of an elephant which has swallowed a ring.

To many readers the last chapter, relating to the industrial applications of rays, will present the greatest novelty. Defects in materials and workmanship are discovered in this way with wonderful ease. A flaw in a weld, for instance, is detected at once, although hidden inches below the surface. During the war much use was made of X-rays in examining the structure of aeroplanes; knots, large resin pockets, defective glueing and poor workmanship are shown up at once by this method, and it is also used for watching the behaviour of the various hidden members, splices and joints of a composite wooden structure whilst it is being subjected to tests.

Another interesting application of X-rays is their use in connexion with pictures. The author quotes various cases in which works by old masters, which have been painted over by later artists, have been detected and brought to light again; while the authenticity of several well-known works of Rembrandt, alleged by some critics to be spurious, has been established beyond a doubt.

ARGHAN: A NEW TEXTILE MATERIAL.

An interesting article is contributed to the *Textile Recorder* by Mr. Alfred S. Moore, on the newly developed textile material known as Arghan. The fibre owes its discovery not to anyone connected directly with textiles. When Sir Henry Wickham, the pioneer of the plantation rubber industry, was exploring South America in search of further supplies of that valuable commodity, he came haphazard upon the arghan in its natural plant habitat. True, the natives were utilising it for harness, belts, bags and other purposes, but their preparation was wasteful, and only in very limited quantities for their own domestic and other purposes.

As a plant it seems to belong to the Maguey or pineapple description, and though he collected specimens, their application did not occur to him until later. Our foreign dependence upon hemp was troubling Mr. Henry Wilson, managing director of the Belfast Ropework Co., Ltd.—the world's greatest rope and twine making concern—and arghan was submitted to him as a possible substitute. At once he

discerned its potentialities in that line. It could be spun into twine absolutely indurate to sea water ravages, and so strong that the twist given by the shop assistant when he had completed tying up his parcel was impossible to break it. In fact, it seemed too good to use merely as twine.

Arghan was then passed into the hands of spinning experts, and they further confirmed Mr. Wilson's opinions. It was found to be fully 50 per cent. more tensile than best hemp or flax. Could it be woven into cloth? Only some minor loom adjustments were necessary, and the result was a magnificent firm cloth. In fact, it has been spun to 25 lea, and cloth has been woven from yarn of this number with great success.

But the problem was how to ensure ample supplies. Even apart from the crude, petty preparation and collection by the South American natives, the transport difficulties would have been nigh impossible.

Moreover, it was desired that the commercial development of arghan should be on all-British lines. With that object then, an expedition was despatched to the South American wilds in winter, 1918, and a goodly supply of roots and suckers was transported to the Federated Malay States, where a nursery had been established. Indeed, the F.M.S. Government were so satisfied that they forthwith placed at the disposal of the Arghan promoters a tract of 30,000 acres, without any premium rent being exacted. And here the plants are in wholesale cultivation. In addition, too, the Indian and Ceylon Governments have set apart similar great areas for its cultivation.

Messrs. Bevan and Cross, the F. M. S. fibre experts, declared arghan unsurpassed in merits by any other fibre submitted to them. As a matter of fact its success has not belied one whit the declaration of Mr. Abraham Montefiore, chairman of the Arghan parent company, who said that the more renowned the expert who had examined the arghan the more enthusiastic was his verdict.

Placed before Lancashire textile manufacturers they proved that it also bleached well, in addition to taking and retaining dye. Especially were the twine and rope making section gratified. So much so that they averred that they, as a body, would take all arghan offered for the making of nets, belting and other cordage. A leading British bleacher goes so far as to prophesy that if only this fibre can be produced at a lower cost than similar flaxen or hemp fabrics it must rival them in use.

One great virtue is that there is no need for the tedious preparation essential in hemp, flax and ramie. The leaves simply split up into long, silky fibres, up to seven feet long, of pearly white colour.

The advent of arghan comes at an opportune moment to give heart to manufacturers troubled

over future flax supplies. Further, no obstacle is put in the way of manufacturers desiring supplies, since Lancashire and Scotch subsidiary companies have been formed to ration these. So far it seems destined to play a great part in replacing cotton for all heavy classes of canvases.

THE AUSTRIAN FILM INDUSTRY.

The Austrian film industry has developed rapidly during the last five years. Owing to favourable geographical position and other conditions essential to the production of films, such as scenery, architecture, and interiors, Vienna has become the centre of this industry for Austria and the States of Succession, as well as the shipping point for the Balkans and the Orient.

In Austria, writes the United States Consul at Vienna, there are about 15 factories producing long and medium length films, six copying establishments, and eight studios with photo rooms, etc. These all are well equipped. Production is steadily increasing, and at present is about 100 middle-length films annually. One-fourth of these are exported. The cost of producing a film of middle length amounts to approximately 25,000,000 Austrian crowns, or nearly £400 at the current rate of exchange.

The requirement of Austria and the States Succession is from 700 to 800 films a year. This demand is met chiefly by imports. In 1921, 55 per cent. of the imports came from Germany, 20 per cent. from the United States, and 25 per cent. from France, Italy, Sweden and Norway.

There are more than 400 cinemas in Austria and 200 in Vienna.

MEETINGS OF OTHER SOCIETIES FOR THE ENSUING WEEK.

MONDAY, NOVEMBER 20. Actuarial, Institute of, at the ROYAL SOCIETY OF ARTS, John Street, Adelphi, W.C., 5 p.m.
British Architects, Royal Institute of, 9, Conduit Street, W., 8 p.m. Mr. L. M. Tyr, "Illuminating Engineering in relation to Architecture."
Brewers, Institute of, at the Institute of Chemistry, 30, Russell Square, W.C. 8 p.m. Mr. W. A. Riley, "Elimination of Waste."
Faraday Society, at the Chemical Society, Burlington House, Piccadilly, W., 7.45 p.m. Annual General Meeting, 8 p.m. (1) Prof. T. M. Lowry, "Intramolecular Ionisation." (2) Mr. C. J. Smith, "On the Viscosity and Molecular Dimensions of Hydrogen Selenide." (3) Mr. W. R. G. Atkins, "The Hydrogen-ion concentration of Natural Waters and Etching Reagents in relation to Action on Metals." (4) Mr. E. W. J. Mardale, (a) "The Scattering of Light by Organosols and Gels of Cellulose Acetate." (b) "Studies of the reversible sol to gel transitions in non-aqueous Systems."
Mechanical Engineers, Institution of, Storey's Gate, Westminster, S.W., 7 p.m. (Graduates' Section.) Mr. H. R. Hookley, "Works Management."
TUESDAY, NOVEMBER 21. Statistical Society, at the ROYAL SOCIETY OF ARTS, John Street, Adelphi, W.C., 5.15 p.m.

Civil Engineers, Institution of, Great George Street, S.W., 6 p.m.
Geographical Society and Alpine Club (Joint Meeting), Central Hall, Westminster, S.W., 8.30 p.m. First Exhibition of the Mount Everest Expedition Cinematograph Films taken by Capt. J. B. Noel.
Anthropological Institute, 50, Great Russell Street, W.C., 8.15 p.m. Miss M. A. Murray, "Recent Excavations in Malta."
Transport, Institute of (Graduates' Section), at the Institution of Electrical Engineers, Victoria Embankment, W.C. Mr. W. B. Gaunt, "The Distribution Organisation of a large Departmental Store."
Chadwick Public Lecture, at the Royal Sanitary Institute, 90, Buckingham Palace Road, S.W., 5.15 p.m. Miss A. D. Muncaster, "Some Hygienic Aspects of Food and Food Preparation."
WEDNESDAY, NOVEMBER 22. United Service Institution, Whitehall, S.W., 3 p.m. Brig.-General W. R. Ludlow, "National Cadets."
St. Paul's Ecclesiastical Society, St. Andrew's Court House, 7, St. Andrew's Street, Holborn, E.C., 8 p.m. Mr. E. W. Harvey Piper, "Gloucester Cathedral."
Geological Society, Burlington House, Piccadilly, W., 5.30 p.m.
Literature, Royal Society of, 2, Bloomsbury Square, W.C., 5 p.m. Mr. E. Fagg, "The Naturalistic Motive in Modern Pictures."
Industrial League and Council, Caxton Hall, Westminster, S.W., 7.30 p.m. Mr. F. S. Butten, "Industrial Co-operation: Works, District, National."
Public Health, Royal Institute of, 37, Russell Square, W.C., 4 p.m. Dr. H. Scurfield, "The Milk Problem, including the use of Dried Milks."
University of London, University College, Gower Street, W.C., 6.15 p.m. Mr. A. W. Flux, "Foreign Exchanges." Lecture III: "Purchasing Power, Parities in Theory and Practice."
Meteorological Society, 19, Cromwell Road, S.W., 5 p.m. (1) Sir Napier Shaw, "Account of the work of the Meteorological Section of the International Union of Geodesy and Geophysics during the meeting at Rome in May, 1922." (2) Mr. A. H. R. Goldie, "Circumstances determining the Distribution of Temperature in the Upper Air under conditions of High and Low Barometric Pressure." (3) Rev. José Aigué, "The Manila Typhoon of May 22nd, 1922."
THURSDAY, NOVEMBER 23. Royal Society, Burlington House, Piccadilly, W., 4 p.m.
British Decorators' Institute of, Painters' Hall Little Trinity Lane E.C., 7.30 p.m. Mr. W. J. Pearce, "How, When and Where come Colour and Ornament."
Antiquaries, Society of, Burlington House, Piccadilly, W., 8.30 p.m.
Historical Society, 22, Russell Square, W.C., 5 p.m. Rev. Prof. J. P. Whitney, "Sir George Prothero—Historian and Teacher."
Camera Club, 17, John Street, Adelphi, W.C., 8.15 p.m. Dr. G. H. Rodman, "The Story of the Cuckoo Spit."
Mechanical Engineers, Institution of (South Wales Branch), 102, St. Mary Street, Cardiff, 6 p.m. Mr. D. Wilson, "Boiler Efficiency under Test and Working Conditions."
Mining and Metallurgy, at the Geological Society, Burlington House, Piccadilly, W., 5.30 p.m.
University of London, at the London School of Economics and Political Science, Houghton Street, W.C., 6 p.m. Sir Frederick Lugard, "Economic and Administrative Problems of the British Tropics." (Lecture I).
FRIDAY, NOVEMBER 24. University of London, University College, Gower Street, W.C., 5.15 p.m. Mr. O. T. Regan, "Problems of Evolution, with special reference to Fishes." (Lecture III).
Mechanical Engineers, Institution of, Storey's Gate, Westminster, S.W., 6 p.m. Adjourned Discussion on Mr. Reavill's paper, "Air Compressors."
Physical Society, Imperial College of Science and Technology, South Kensington, S.W., 5 p.m.

Announcements intended for insertion in this list must be received at the SOCIETY'S Office not later than the Monday of the week preceding the meeting.

INDEX TO VOL. LXX.

A.

- Acid mixing, 307
 Acworth, Sir William M., *disc.*, Indian railway gauge policy, 540
 Adams, Professor Henry, *letter*, coast erosion, 409
 Advertising in South Africa, 442
 Aeroplanes as scarecrows, 184
 Agriculture in Morocco, 698
 ————South Africa, 308
 Alkin, Dr. W. A., *disc.*, speech training, 321
 Air congress, international, 1923, 795
 ————traffic from Paris, 21
 Airship service, an imperial, *paper* by A. H. Ashbolt, 102
 Albert medal (*see* "Medals")
 Alcohol in relation to industrial hygiene and efficiency, *paper* by Sir Thomas Oliver, 445
 Allen, Col. Hon. Sir James, *chair*, New Zealand, 463, 473
 Amritsar, trade conditions in, 407
 Anderson, Bruce, *disc.*, titanium oxide, 564
 Anstruther, G. Elliot, *disc.*, photo-sculpture, 227
 Appleton, W. A., *paper*, the proper functions of trade unions, 377; silver medal awarded for his *paper*, 595
 Architecture, Cambridge school, of, 233
 ————, modern, of Cambridge, *paper* by T. H. Lyon, 49
 Arghan : A new textile material, 877
 Armstrong, Sir Charles H., *disc.*, the timbers of India and Burma, 250; *disc.*, Indian railway gauge policy, 541
 Armstrong, Professor H. E., F.R.S., *disc.*, some solved and unsolved problems of gas works chemistry, 304; *disc.*, lignites and brown coals, 356; *letter*, surface combustion, 375; *paper*, the indigo situation in India, 409; silver medal awarded for his *paper*, 595
 Armstrong-Jones, Sir Robert, *chair*, alcohol in relation to industrial hygiene and efficiency, 445, 456
 Arnold, Sir T. W., *Sir George Birdwood Memorial Lecture*, Indian painting and Muhammadan culture, 617
 Art galleries, provincial, *paper*, by Lawrence Haward, 631
 Artificial flower industry of Germany, 767
 Artists' oil colours, experiments on the permanency of, 432
 Asbestos mining in Quebec, 627
 Ashbolt, A. H., Society's silver medal presented to, 24; *paper*, an imperial airship service, 102
 Ashworth, S. H., *letter*, electric power in the factory, 735
 Askwith, Lord, elected chairman of council, 617

B.

- Babassu nuts, 507
 Bailey, J., *disc.*, the problem of provincial galleries and art museums, 640
 Bailie, Andrew Francis, Society's silver medal presented to, 24
 Balnes, Sir Frank, *chair*, preservation of stone, 123, 133
 Baker, John, *disc.*, the proper functions of trade unions, 388
 Baker, Robert Percival, *disc.*, surface printing by rollers in the cotton industry, 268
 Bamboo, East African, 702
 Barker, Sir Francis Henry, *obituary*, 231
 Barnes, Sir George S., appointed a member of the Indian Section Committee, 705
 Barnes, Kenneth, *disc.*, speech training, 321
 Batten, John, *disc.*, artists' oil colours, 436; *disc.*, titanium oxide, 563
 Bayley, Sir Charles S., *disc.*, lignites and brown coals, 357; *disc.*, Indian painting and Muhammadan culture, 626
 Bazaar goods for the Red Sea district, 644
 Bedford, Sir Charles H., Society's silver medal presented to, 24
 Beef, jerked, 400
 Bellby, Sir George, F.R.S., *chair*, the power resources of Ireland, 603
 Belgian Ambassador, *chair*, literature and international relations, 161
 ————Congo, trade of, 232
 ————, transport facilities in, 269
 Bell, Dr. Alexander Graham, *obituary*, 689
 Bellairs, Commander Carlyon, M.P., *disc.*, lignites and brown coals, 356
 Bennett, Sir Thomas, M.P., *disc.*, imperial wireless communication, 522; *disc.*, Indian railway gauge policy, 544
 Best, William Newton, *obituary*, 566
 Bigland, Alfred, M.P., *disc.*, an imperial airship service, 120
 Binyon, Laurence, *disc.*, literature and international relations, 168
 Bitumen in Palestine, 566
 Blanket trade of the Orinoco Valley, 810
 Bone, Professor W. A., F.R.S., *paper*, lignites and brown coal and their importance to the Empire, 342; *letter*, surface combustion, 359; silver medal awarded for his *paper*, 595

 CANTOR LECTURES.—Notices of publication of reprint. 857; annual report, 593
 1st Course:—"Processes of engraving and etching," by Professor Arthur M. Hind, O.B.E., M.A., 755; *syllabus*, 22
 2nd Course:—"Inks," by C. Ainsworth Mitchell, M.A., F.I.C., 647; *syllabus*, 144
 3rd Course:—"The mechanical design of scientific instruments," by Professor Alan F. C. Pollard, F.Inst.P., A.M.I.E.E., 769, 783, 797; *syllabus*, 144
 4th Course:—"The constituents of essential oils," by Lionel Guy Radcliffe, M.Sc.Tech., F.I.C., 811, 825, 843
 Carey, A. E., *letter*, coast erosion, 500
 Carpenter, Dr. Charles, *disc.*, some solved and unsolved problems in gasworks chemistry, 304
 Carpets, Persian, 800
 Cassava, improvement in method of planting, 45
 Cement manufacture in the Punjab, 505
 Chadwick, T. D., *disc.*, the indigo situation in India, 420
 Cheese production in Greece, 221
 Chemical industries of India, 270
 ———-researches for key industries in India, 402
 China's economic position, 169
 Chitrol, Sir Valentine, Hindu painting and Muhammadan culture, 626
 Chota Nagpur and Orissa, 322
 Cinchona bark and myrobals, Indian, 662
 Cinnamon, 289
 Clerk, Sir Dugald, F.R.S., Society's silver medal (1917) presented to, 23; vote of thanks to Chairman, opening meeting, 43; Albert medal awarded to, 527; presented to, 585
 Clinton, Lord, *chair*, the timbers of British Columbia, 273, 282
 Coal waste, utilisation of, on German railways, 856
 Coast erosion and its prevention, *paper* by Professor B. R. Matthews, 477
 Coca production in Java, 644
 Cockrell, S. C., *disc.*, modern architecture in Cambridge, 61
 Cocoa-industry of Orinoco delta, 768
 ———-raw, insect pests of, 443
 Coldstream, W., *letter*, the timbers of India and Burma, 253
 Coles, Dr. D. A., *disc.*, industrial fatigue research, 17
 Collis, Professor E. L., *disc.*, industrial fatigue research, 18
 Colson, C. H., *disc.*, coast erosion, 497
 Conway, Sir Martin, *chair*, the design of repeating patterns for decorative work, 578
 Cook, Rt. Hon. Sir Joseph, appointed a member of the Dominions and Colonies Section Committee, 273
 Corbett, J. S., *disc.*, the timbers of British Columbia, 284
 Corner, Dr. H., *disc.*, the biological theory of sex, 210
 Cottages, experimental designs, 508
 Cotton, Egyptian, yield of, 324
 ———-growing in the Argentine Chaco, 442
 ———-in the Belgian Congo, 810
 ———-trade and India, 393
 Cottons, surface printing of, *paper* by Arthur Wilcock, 260
 Council, 1; annual report, 597; elected, 599; P. M. Evans elected a member and vice-president, 173; Lord Askwith elected chairman, 617; Sir Aston Webb elected a member and vice-president, 811
 Cramp, Dr. William, Society's silver medal presented to, 24
 Crowley, Dr. J. F., *paper*, the use and advantages of electric power in the factory, 663, 677, 691; silver medal awarded for his paper, 595; *disc.*, the power resources of Ireland, 614
 Crowther, Richard William, *obituary*, 676
 Currie, Sir James, *disc.*, Tanganyika Territory, 751
 Curtis, Sir George S., Society's silver medal presented to, 24
 Czecho-Slovakia, iron cultivation in, 202
 ———-natural resources of, 630
- D.**
- Dairy industry of New Zealand, 310
 Dakin, F., *disc.*, titanium oxide, 563
 Dale, Hylton B., the woodmongers' company, 816
 Davenport, George, presentation to, 585
 Dawson, Commander Sir Trevor, *disc.*, an imperial airship service, 120
 de Jong, H. J., *disc.*, trade with the Netherlands East Indies, 181
 Dent, Edward, *chair*, trade with the Netherlands East Indies, 180
 Desch, Prof. Cecil H., *letter*, preservation of stone, 139
 de Segundo, E. C., *letter*, the proper functions of trade unions, 390
 Design of repeating patterns for decorative work, *paper* by Major Percy MacMahon, F.R.S., 567
 Devonshire, Duke of, *chair*, British Columbia: the awakening of the Pacific, 146, 151
 Diamond mining in South Africa, 441
 DOMINIONS AND COLONIES SECTION (see also "Dominions and Colonies and Indian Sections"):—Meeting of committee, 187; annual report, 591; list of committee, 691
 1st Meeting:—"British Columbia: the awakening of the Pacific," by F. C. Wade, B.A., K.C., 146
 2nd Meeting:—"The timbers of British Columbia," by William Turnbull, 273
 3rd Meeting:—"New Zealand," by Lieut.-Col. Sir Thomas Blibe Robinson, G.B.E., K.C.M.G., 463
 4th Meeting:—"The Tanganyika Territory," by Major Sir Humphrey Leggett, D.S.O., R.E., 737
 DOMINIONS AND COLONIES AND INDIAN SECTIONS—Joint meetings (see also "Dominions" and "Indian"), Annual report, 591:—
 1st meeting:—"An imperial airship service," by A. H. Ashbolt, 102
 2nd Meeting:—"Lignites and brown coals and their importance to the Empire," by William Arthur Bone, D.Sc., Ph.D., F.R.S., 342
 3rd Meeting:—"Imperial wireless communication," by Professor W. H. Eccles, D.Sc., F.R.S., 509
 Drawn-work, embroidery and lace industries at Swatow, 43
 ———-in the Canaries, 855

Duncan, Mrs. James, *disc.*, the problem of provincial galleries and art museums, 642
 Duplex-coupler pianoforte, *paper* by Emanuel Moor, 365
 Dyer, S., *letter*, coast erosion, 501
 Dyes from Kaoliang bran, 548

E.

Eccles, Professor W. H., F.R.S., *paper*, imperial wireless communication, 509; silver medal awarded for his *paper*, 596
 Eccles, W. McAdam, *disc.*, alcohol and industrial efficiency, 457
 Edmunds, Henry, *letter*, photo-sculpture, 228
 Edmunds, Howard Maurice, *paper*, photo-sculpture, 224; silver medal awarded for his *paper*, 595
 Electric power in the factory, the use and advantages of, *paper* by Dr. J. F. Crowley, 663, 677, 691
 Electricity and agriculture, 367
 Elphinstone, A., *disc.*, artists' oil colours, 438
 Elveden, Viscount, *chair*, lignites and brown coals, 355
 Engraving and etching, processes of, *Cantor Lectures* by Arthur M. Hind, 755
 Essential oil and perfume industry in Italy, 736
 ——— oils, the constituents of, *Cantor Lectures* by Lionel Guy Radcliffe, 811, 825, 813
 Evans, Edward Victor, *paper*, some solved and unsolved problems in gas works chemistry, 292; silver medal awarded for his *paper*, 595
 Evans, Constructor-Commander H. B. Wyn, *disc.*, an imperial airship service, 119
 Evans, P. M., elected a member of the council and vice-president, 173
 EXAMINATIONS, ROYAL SOCIETY OF ARTS, 1922, *notices*, 631, 755; annual report, 596; report on, 857
 Exchange stabilisation, *paper* by Oswald T. Falk, 395
 EXHIBITION:—
 Bradlan, 222, 394

F.

Falence and porcelain industry of Provence, 168
 Falk, Oswald T., *paper*, exchange stabilisation, 395
 Fibre resources of Colombia, 439
 Fibroterrite, 508
 Film industry of Austria, 878
 Finance, annual report, 598
 Financial statement for 1921, 549
 Flax seed, production of a new variety, 300
 Fleming, Professor J. A., *Trueman Wood Lecture*, radio-telegraphy, 66
 Fletcher, George, *paper*, the power resources of Ireland, 604
 Flies and child mortality, by E. Halford Ross, 873
 Fogarty, Miss Elsie, *disc.*, speech training, 319
 Food paste industry in Algeria, 754
 Foot, J. Taylor, *disc.*, photo-sculpture, 227
 Foucar, A. F. E., *disc.*, exchange stabilisation, 401
 Fox, Cyril S., *letter*, lignites and brown coals, 358
 Fox, Dr. J. J., *disc.*, preservation of stone, 136
 Fox, Dr. H. Fortescue, *letter*, industrial fatigue research, 62
 France, F. H., *disc.*, the timbers of India and Burma, 252
 Fraser, J. M., *disc.*, trade with the Netherlands East Indies, 180
 Fruit cultivation in Czecho-Slovakia, 202
 Fryer, Sir Frederic W. R., *obituary*, 287
 Fuel research, 233
 Fur farming in Canada, 628
 Furniture, 17th and 18th century, gift of to Victoria and Albert Museum, 842

G.

Galleries and art museums, provincial, the problem of, *paper* by Lawrence Haward, 631
 Gambler, 532
 Gane, Charles, *disc.*, exchange stabilisation, 399
 Garton, R. H., *disc.*, surface printing by rollers in the cotton industry, 268
 Gas works chemistry, some solved and unsolved problems in, *paper* by E. V. Evans, 292
 Gibson, J. A., *disc.*, titanium oxide, 564
 Gillan, Sir B. W., *chair*, Indian railway gauge policy, 538
 Glove industry in Czecho-Slovakia, 642
 Glover, F., *disc.*, some solved and unsolved problems in gas works chemistry, 304

Goadby, Sir Kenneth Weldon, Society's silver medal presented to, 24
 Gozo, industries of, 662
 Graham, W., M.P., *chair*, industrial fatigue research, 2, 19
 Grantham, R. F., *letter*, coast erosion, 501
 Grasses for paper making, 257
 Gray, Captain I. J., *disc.*, coast erosion, 498
 Grigg, Lieut.-Col. Sir Edward W. M., Society's medal presented to, 24
 Groom, Professor Percy, *letter*, Indian timbers, 269; *disc.*, the timbers of British Columbia, 288
 Gum, Kauri, industry in New Zealand, 68, 810
 ——— myrrh, production of, in the Red Sea district, 782

H.

Hair-net industry of China, 767
 Haldane, Dr. J. S., F.R.S., *disc.*, some solved and unsolved problems in gas works chemistry, 303
 Hall, Sir Daniel, F.R.S., Society's silver medal (1920) presented to, 24
 Hall, J. J., *disc.*, the proper functions of trade unions, 389
 Halsbury, Earl of, *obituary*, 98
 Hamilton, Admiral de Courcy, *dis.*, Tanganyika Territory, 752
 Hancock, Walter C., *disc.*, titanium oxide, 562
 Hankin, Dr. E. H., *disc.*, the design of repeating patterns for decorative work, 580
 Hannay, A. A., *disc.*, the timbers of India and Burma, 248
 Hannon, P. J., M.P., appointed a member of the Dominions and Colonies Section, 123
 Hardie, T., *disc.*, some solved and unsolved problems in gas works chemistry, 306
 Hare, Sir Lancelot, *disc.*, exchange stabilisation, 399; *disc.*, the indigo situation in India, 428; *obituary*, 825
 Harker, Dr. J. A., F.R.S., *disc.*, the power resources of Ireland, 613
 Harmer, Sir Sidney, F.R.S., *disc.*, restoration and preservation of objects at the British Museum, 333
 Harrison, Charles, *disc.*, titanium oxide, 563
 Hart, Sir George S., *disc.*, the timbers of India and Burma, 250; *disc.*, the timbers of British Columbia, 285
 Hat industry in Argentina, 288
 Haward, Lawrence, *paper*, the problem of provincial galleries and art museums, 631; silver medal awarded for his *paper*, 595
 Headley, Lord, *chair*, coast erosion, 495
 Heath, Sir Frank, *disc.*, restoration and preservation of objects at the British Museum, 334
 Heaton, Noel, *paper*, preservation of stone, 124; *disc.*, artists' oil colours, 436; *paper*, the production of titanium oxide and its use as a paint material, 552
 Heitland, Percival, *disc.*, British Columbia, 153
 Hind, Professor Arthur M., *disc.*, the problem of provincial galleries and art museums, 641; *Cantor Lectures*, processes of engraving and etching, 755
 Hodgkinson, Frederick, *letter*, irrigation enterprise in India, 735
 Hogben, Dr. L. T., *disc.*, the biological theory of sex, 218
 Holland, Sir Thomas H., appointed a member of the Indian section committee, 273; *chair*, the indigo situation in India, 409, 425; *disc.*, Indian railway gauge policy, 542; *disc.*, titanium oxide, 562
 Holmes, Sir Charles John, *chair*, provincial galleries and art museums, 638
 Hopkinson, Dr. Edward M.P., *obituary*, 202
 Howard, Alexander L., *paper*, the timbers of India and Burma, 238
 Howard, David Lloyd, *disc.*, trade with the Netherlands East Indies, 181
 Howe, J. Allen, *disc.*, preservation of stone, 136
 Hubbard, George, *disc.*, preservation of stone, 137
 Hughman, E. M., *disc.*, the timbers of India and Burma, 252
 Hunter, Sir George, *disc.*, alcohol and industrial efficiency, 459
 Hunter, Mrs. M., *disc.*, the biological theory of sex, 219
 Hurd, Percy, M.P., *disc.*, an imperial airship service, 121; *disc.*, British Columbia: the awakening of the Pacific, 152
 Huxley, Julian S., *paper*, the biological theory of sex, 188, 206
 Hydro-electric power development in Latvia, 548

I.

- India, American trade competition in, 170
 — chemical industries of, 270
 — irrigation enterprise in, *paper*, by F. W. Woods, 705, 719
 — purchasing power of native population, 393
 — research for key industries in, 402

Indian Antiquary, 234

MEDALS :—

- Albert, list of awards, 291; awarded to Sir Dugald Clerk, 527; presentation by H. R. H. the Duke of Connaught, 585; annual report, 594; Society's silver medals for *papers* read in 1920-21, presented, 23; annual report, 595

MEETINGS OF THE 168TH SESSION :—

- ANNUAL MEETING, *notice*, 527; report of meeting, 585
 CANTOR LECTURES (*see* "Cantor")
 DOMINIONS AND COLONIES SECTION (*see* "Dominions")
 INDIAN SECTION (*see* "Indian")
 INDIAN AND DOMINIONS AND COLONIES SECTIONS (*see* "Indian and Dominions")
 JUVENILE LECTURES (*see* "Mann")
 SHAW LECTURE (*see* "Shaw"); annual report, 594
 SIR GEORGE BIRDWOOD MEMORIAL LECTURE (*see* "Sir George Birdwood")
 TRUEMAN WOOD LECTURE (*see* "Trueman Wood")

MEETINGS, ORDINARY :—Annual report, 586

- 1st Meeting :—Opening address (wireless telegraphy) by Alan A. Campbell Swinton, F.R.S., M.Inst.C.E., M.I.E.E., M.I.Mech.E., Chairman of the Council of the Society, 23
 2nd Meeting :—"The work of the Industrial Fatigue Research Board and its applications to industry," by D. R. Wilson, M.A., 2
 3rd Meeting :—"Modern buildings in Cambridge and their architecture," by T. H. Lyon, M.A., 49

- 4th Meeting :—"The coming of age of long distance radiotelegraphy and some of its scientific problems," by J. A. Fleming, D.Sc., F.R.S. (Trueman Wood Lecture), 66
- 5th Meeting :—"The preservation of stone," by Noel Heaton, B.Sc., 123
- 6th Meeting :—"Literature and international relations," by Emile Cammaerts, 161
- 7th Meeting :—"Trade with the Netherlands East Indies," by Sir Walter Beaupré Townley, K.C.M.G., 174
- 8th Meeting :—"Some recent advances in the biological theory of sex," by Julian S. Huxley, M.A., 187, 206
- 9th Meeting :—"Photo-sculpture," by Howard M. Edmunds, 224
- 10th Meeting :—"Surface printing by rollers in the cotton industry," by Arthur Wilcock, 260
- 11th Meeting :—"Some solved and unsolved problems in gas works chemistry," by E. V. Evans, F.I.C., 292
- 12th Meeting :—"The need of speech training and the necessity for a national conservatoire," by Cloudestley Brereton, 309
- 13th Meeting :—"The restoration and preservation of objects at the British Museum," by Alexander Scott, Sc.D., D.Sc., M.A., F.R.S., 327
- 14th Meeting :—"The duplex-coupler pianoforte," by Emanuel Moor, 363
- 15th Meeting :—"The proper functions of trade unions," by W. A. Appleton, C.B.E., 377
- 16th Meeting :—"Certain aspects of the problem of exchange stabilisation," by Oswald T. Falk, C.B.E., 395
- 17th Meeting :—"The late Mr. Holman Hunt's experiments on the permanency of artists' oil colours," by Professor A. P. Laurie, M.A., D.Sc., F.R.S.E., 432
- 18th Meeting :—"Alcohol in relation to industrial hygiene and efficiency," by Sir Thomas Oliver, M.D., F.R.C.P. (Shaw Lecture), 445
- 19th Meeting :—"Coast erosion and its prevention," by Professor E. R. Matthews, Assoc.M.Inst.C.E., F.R.S. (Ed.), F.G.S., 477
- 20th Meeting :—"The use and advantages of electric power in the factory," by J. F. Crowley, D.Sc., B.A., M.I.E.E., 663, 677, 691
- 21st Meeting :—"The production of titanium oxide and its use as a paint material," by Noel Heaton, B.Sc., 552
- 22nd Meeting :—"The design of repeating patterns for decorative work," by Major Percy A. MacMahon, R.A., LL.D., Sc.D., F.R.S., 507
- 23rd Meeting :—"The power resources of Ireland," by George Fletcher, F.G.S., M.R.I.A., 603
- 24th Meeting :—"The problem of provincial galleries and art museums, with special reference to Manchester," by Lawrence Haward, M.A., 631
- Meik, C. S., *disc.*, coast erosion, 496; *letter*, 499
- Mellor, Donald, *disc.*, Tanganyika Territory, 751
- Menthol production in Japan, 204
- Metallurgical Process: new German invention, 429
- Metcalf, Sir Charles, H. T., Bt., appointed a member of the Dominions and Colonies Section Committee, 2
- Meyer, Sir William S., *chair*, the timbers of India and Burma, 237, 249; *obituary*, 842
- Milk products, manufacture of, in Australia, 323
- Mills, Sir James, *disc.*, New Zealand, 474
- Mineral resources of Czecho Slovakia, 140
- Ecuador, 628
- Mitchell, C. Ainsworth, *Cantor Lectures*, inks, 647
- Mitchell, Dr. Peter Chalmers, F.R.S., *chair*, some recent advances in the biological theory of sex, 187, 217
- Molasses, blackstrap, 359
- Montagu of Beaulieu, Lord, *chair*, an imperial airship service, 102, 120; appointed a member of the Indian section committee, 409; *disc.*, Indian railway gauge policy, 530; *obituary notice* of Viscount Northcliffe, 703
- Moor, Emanuel, *paper*, the duplex-coupler pianoforte, 365
- Mother of pearl industry in Bethlehem, 796
- Munby, Alan E., *disc.*, preservation of stone, 137
- Murray, John, M.P., *chair*, the proper functions of trade unions, 377, 385
- Myers, Hon. A. M., *disc.*, New Zealand, 474
- N.
- Netherlands East Indies, trade with, *paper* by Sir Walter Townley, 174
- Newbolt, Sir Henry, *chair*, speech training and the necessity for a national conservatoire, 316
- New Zealand, *paper* by Lieut.-Colonel Sir Thomas Blube Robinson, 464
- Nickel resources of Celebes, 157
- Nipa palm, 523
- Non-ferrous metals research, 307
- Norman, Sir Henry, Bt., M.P., *disc.*, Imperial wireless communication, 521
- Northcliffe, Viscount, *obituary*, 703
- Norway, industrial conditions in, 824

Patagonia, 601

Patchell, W. H., *disc.*, electric power in the factory, 693

Patrick, A., *disc.*, alcohol and industrial efficiency, 460

Peanut industry in Egypt, 270

Pearls, "cultured," 307

production of, in Japan, 394

Peel, Viscount, *chair*, Indian painting and Muhammadan culture, 625

Pepper-growing in Sarawak, 643

Perkin, Dr. F. Mollwo, *disc.*, lignites and brown coals, 356

Peter Le Neve Foster prize, *notice*, 445: annual report, 597

Petrol, automatic supply of, for automobiles, 158

Phosphate production in Egypt, 547

Photo-sculpture, *paper*, by Howard M. Edmunds, 224

Pianoforte, duplex-coupler, *paper* by Emanuel Moor, 365

Piggott, Sir Francis, *disc.*, the design of repeating patterns for decorative work, 578

Pine timber, production of, in South-Western France, 524

Platinum in Brazil, 508

Pollard, Professor Alan F. C., *Cantor Lectures*, the mechanical design of scientific instruments, 769, 783, 797

Portland cement as a fire extinguisher, 782

Potash, Alsatian, 566

deposits in Catalonia, 630

Pottery, early Chinese, exhibit of, at Victoria and Albert Museum, 46

Poultry industry of the United Kingdom, 602

Power resources of Ireland, *paper* by George Fletcher, 604

Powys, A. R., *disc.*, modern architecture in Cambridge, 60; *disc.*, preservation of stone, 137

Prain, Lieut.-Col. Sir David, *disc.*, the timbers of British Columbia, 283

Preston, Sidney, *letter*, Indian railway gauge policy, 544; *disc.*, irrigation enterprise in India, 731

Prune growing in Bedfordshire, 121

Pugh, Arthur, *disc.*, industrial fatigue research, 16

Q.

Quinine cultivation in the Philippines, 394

R.

Radcliffe, Lionel Guy, *Cantor Lectures*, the constituents of essential oils, 811, 825, 843

Radiotelegraphy, *Trueman Wood Lecture*, by Professor J. A. Fleming, 66

Railway gauges in India, *paper* by F. G. Royal-Dawson, 527

Raitt, William, Society's silver medal, presented to, 24

Ramie cultivation in China, 629

Read, Sir Hercules, *disc.*, the design of repeating patterns for decorative work, 580

Reh salts, 768

Reid, Arthur H., *obituary*, 876

Reid, Walter F., *disc.*, restoration and preservation of objects at the British Museum, 336; *disc.*, artists' oil colours, 434

Renold, O. G., *disc.*, electric power in the factory, 694

Repeating patterns for decorative work, the design of, *paper* by Major Percy A. MacMahon, F.R.S., 567

Ricardo, Halsey, *disc.*, modern architecture in Cambridge, 60

Rice planting in Sarawak, 766

Richmond, Lieut.-Colonel V. C., *disc.*, an imperial airship service, 117

Robinson, Lieut.-Col. Sir Thomas B., *paper*, New Zealand, 464

Robson, G. C., *disc.*, the biological theory of sex, 218

Ronaldshay, Earl of, *disc.*, Indian painting and Muhammadan culture, 625

Roofing-tiles in East Africa, 375

Rorke, Alfred, *disc.*, exchange stabilisation, 399; *disc.*, alcohol and industrial efficiency, 459

Rowland, Dr. M. J., *disc.*, the biological theory of sex, 218

Royal-Dawson, F. G., *paper*, the need for an all-India gauge policy, 527

Rubber industry of Bolivia, 99

Ryan, G. M., *letter*, the timbers of India and Burma, 254; *letter*, the timbers of British Columbia, 287; *letter*, road transport in India, 545

S.

Sadler, Lieut.-Col. Sir James Hayes, *obituary*, 439

Sampson, George, *disc.*, speech training, 320

Samuel, J. W., *disc.*, speech training, 321

Santa Cruz, resources and trade of, 371

Santley, Sir Charles, *obituary*, 781

Santonin, 233

Scholes, Percy A., *chair*, the duplex-coupler pianoforte, 363, 365

Scientific instruments, the mechanical design of, *Cantor Lectures*, by Professor Alan F. C. Pollard, 769, 783, 797

Scott, Dr. Alexander, *paper*, the restoration and preservation of objects at the British Museum, 327

Seaweed industry in Holland, 525

Seligman, Charles, *disc.*, exchange stabilisation, 399

Seyn, Arthur, *disc.*, the problem of provincial galleries and art museums, 641

Sex, some recent advances in the biological theory of, *paper*, by Julian S. Huxley, 188, 206

Sharman, W., *disc.*, speech training, 321

Shaw Lecture, alcohol in relation to industrial hygiene and efficiency, by Sir Thomas Oliver, 445

Shepherd, M. L., appointed a member of the Dominion and Colonies Section Committee, 2; *disc.*, an imperial airship service, 117

Silk, artificial, in Italy, 642

cultivation in Brazil, 443

Simpson, F. H. H., *disc.*, exchange stabilisation, 400

Sir George Birdwood, *Memorial Lecture*, Indian painting and Muhammadan culture, by Sir T. W. Arnold, 617

S' Jacob, F. B., *disc.*, trade with the Netherlands East Indies, 181

Slater, John, *disc.*, modern architecture in Cambridge, 61; vote of thanks to chairman, annual meeting, 600

Smith, Sir Cecil Harcourt, *chair*, surface printing by rollers in the cotton industry, 266

Smith, J. Cruickshank, *disc.*, titanium oxide, 563

Smith, Capt. Sir Ross Macpherson, *disc.*, an imperial airship service, 117

Snell, Sir John F. C., *chair*, electric power in the factory, 663, 692

Soames, Mrs. A., *disc.*, the biological theory of sex, 219

Society's house, subscriptions towards purchase and renovation of, 47, 150, 259, 431, 603, 871; annual report, 586

South Africa, drought in, 768

Sparks, Colonel H., *disc.*, electric power in the factory, 695

Speech training, *paper*, by Cloudeley Brereton, 309

Squire, Miss Rose E., *disc.*, alcohol and industrial efficiency, 459

Stamping processes in Great Britain and the United States, 506

Starr, William J., *obituary*, 287

Steele, F. E., *disc.*, exchange stabilisation, 398

Stevens, Theodore, *disc.*, the power resources of Ireland, 613

Stone, preservation of, *paper*, by Noel Heaton, B.Sc., 124

Stoop, F. C., *disc.*, trade with the Netherlands East Indies, 180

Stopes, Dr. Marie C., *disc.*, lignites and brown coals, 355

Sturdy, Colonel Robert J., Society's silver medal presented to, 24

Strakosch, Sir Henry, *disc.*, exchange stabilisation, 400

Stringed instruments, manufacture of, at Nagoya, 288

Sugar refining in India, 810

Summers, Dr. T., *disc.*, irrigation enterprise in India, 732

Sutcliffe, W., *disc.*, electric power in the factory, 695

Swinton, Alan A. Campbell, F.R.S., vote of thanks to anonymous donor of £30,000 towards premises fund and opening address (wireless telegraphy), 25; *chair*, radiotelegraphy, 66, 96; *disc.*, literature and international relations, 168; *chair*, photo-sculpture, 226, 228; *disc.*, imperial wireless communication, 518; *chair*, titanium oxide, 552, 564; *chair*, annual meeting, 585, 598; *obituary notice* of Dr. Alexander Graham Bell, 689

Sydenham, Lord, *disc.*, irrigation enterprise in India, 730

Szechuen, road development in, 602

T.

- Tanganyika Territory, *paper* by Major Sir Humphrey Leggett, 737
 Tar industry of Finland, 44
 Taylor, Major Blake, *disc.*, Tanganyika Territory, 752
 Tea oil, 526
 — plant, Chinese, cultivation of, in Paraguay, 158
 Thomas, Carmichael, vote of thanks to chairman, annual meeting, 600
 Thomas, Cecil, *disc.*, photo-sculpture, 226

 Thomas, Mrs. R. Haig, *disc.*, the biological theory of sex, 218
 Thomson, H. Lyon, *disc.*, photo-sculpture, 227
 Thread twisting machine, 339
 Throne of Emperor Ch'ien Lung, 662
 Timber in the maritime province of Siberia, 781
 — resources of the Belgian Congo, 325
 — trade in Esthonia, 808
 Timbers of India and Burma, *paper*, by Alexander L. Howard, 238; *letter* by Professor Percy Groom, 269
 — and paper materials, 289
 — of British Columbia, *paper* by William Turnbull, 274
 Titanium oxide, *paper*, by Noel Heaton, 552
 Tobacco, cultivation of, in Java, 404
 — growing in the British Empire, 752
 Townley, Sir Walter, *paper*, trade with the Netherlands East Indies, 174
 Town planning, 796
 Tractors, use of, in Peru, 324
 Trade unions, the proper functions of, *paper*, by W. A. Appleton, 377
 Transport: historical celebrations, 376
 Troup, F. W., *disc.*, preservation of stone, 138
 Troup, Professor R. S., *disc.*, the timbers of India and Burma, 249
 Trueman Wood Lecture, long distance radio-telegraphy, by Dr. J. A. Fleming, 66
 Turnbull, William, *paper*, the timbers of British Columbia, 274
 Turner, Laurence A., *disc.*, preservation of stone, 138
 Turpentine and rosin, production of, in Greece, 718

V.

- Vassar-Smith, Sir Richard Vassar, *obituary* 676
 Voelcker, Dr. J. Augustus, *disc.*, the indigo situation in India, 427
 Voysey, Miss E. B., *disc.*, industrial fatigue research, 19

W.

- Wade, F. C., *paper*, British Columbia: the awakening of the Pacific, 146; silver medal awarded for his paper, 595
 Walker, Arthur, *obituary*, 170
 Wallis, Sir Whitworth, *disc.*, provincial galleries and art museums, 639

- Walmisley, A. T., *letter*, coast erosion, 502
 Walton, Cecil, *disc.*, the proper functions of trade unions, 387
 Walton, Hon. Sir Edgar H., appointed a member of dominions and colonies section, 2
 Wang, C. Y., Peter Le Neve Foster prize awarded to, 445
 Waring, F. J., *letter*, the timbers of India and Burma, 254; *letter*, coast erosion, 503; *disc.*, Indian railway gauge policy, 544
 Water power in India, 440
 — the Riviera, 158
 — resources of the United Kingdom, 153
 Watson, G., *disc.*, the indigo situation in India, 428
 Wattles, South Indian, 406
 Wax (Carnauba), exports from Brazil, 768
 — production in the Aden district, 768
 Webb, Sir Aston, P.R.S., *chair*, artists' oil colours, 487; elected a member of the council and vice-president, 811
 Weller, H. O., *disc.*, preservation of stone, 138; *disc.*, titanium oxide, 562
 Whale and seal oil industry in Argentina, 630
 Whaling industry, 339
 Whitaker, W., F.R.S., *disc.*, coast erosion, 496
 Wigglesworth, Alfred, *disc.*, Tanganyika Territory, 750
 Wigglesworth, Frederick, *disc.*, exchange stabilisation, 399
 Wilcock, Arthur, *paper*, surface printing by rollers in the cotton industry, 260
 Williams, W. M. J., *disc.*, trade with the Netherlands East Indies, 182
 Wilson, D. R., *paper*, industrial fatigue research, 3
 Wilson, George B., *disc.*, alcohol and industrial efficiency, 458
 Wilson, Sir James, *letter*, irrigation enterprise in India, 732
 Wireless chain, 156
 — *paper* by Professor W. H. Eccles, F.R.S., 509
 — telegraphy (chairman's address) by Alan A. Campbell Swinton, 25
 — coming of age of, *Trueman Wood Lecture*, by Dr. J. A. Fleming, F.R.S., 66
 — David Hughes's apparatus, 376
 Woodhouse, Thomas, *disc.*, electric power in the factory, 694
 Woodmongers, the worshipful company of, 816
 Woods, F. W., *paper*, irrigation enterprise in India, 705, 719
 Wool industry of China, 781
 Woolcock, W. J. U., M.P., *chair*, some solved and unsolved problems in gas works chemistry, 302
 Woollen industry of Japan, 184
 Wyon, Allan G., *disc.*, photo-sculpture, 227

X.

- Xarque (Jerked beef) industry of Brazil, 460

Y.

- Yate, Sir Charles K., Bt., *disc.*, British Columbia, 153; *disc.*, the timbers of India and Burma, 253; *disc.*, irrigation enterprise in India, 732

ARMSTRONG SIDDELEY

Six Cylinder Cars

HE favourable impression created by the Armstrong Siddeley 18 h.p. 6 Cylinder on its first appearance has been confirmed by its road performance. We continue to receive letters like the following:

West Byfleet

"... For several days now I have been intending to write and let you know how extremely pleased I am with the 18 h.p. A.S. Car. Its road performance is much better than I expected. Three times last week I drove up to town and back—a distance of 53 miles—and each time the consumption measured exactly two gallons. Saturday I did 131 miles to Brighton and back, encountering some stiff hills, and the consumption was 5½ gals.

Both my wife and myself feel we have the car under complete control at all speeds. The detail, finish, and absence of complications, make the car, I consider, ideal for an owner driver. One simply has to press the button, and beyond oil, petrol and water, the Armstrong Siddeley Company have done the rest. I thoroughly endorse your statement, 'YOU CANNOT BUY A BETTER CAR.'"

Royal Society for the Encouragement of Arts, Manufactures and Commerce.

The Royal Society of Arts was founded in 1754, and incorporated by Royal Charter in 1847, for the Encouragement of the Arts, Manufactures, and Commerce of the country.

At present the Society numbers about 4,000 Fellows. The annual subscription is Three Guineas, the life subscription Thirty Guineas. There is no entrance fee.

Fellows are entitled to be present at all the meetings of the Society. These include the Ordinary Meetings, held every Wednesday during the Session, when papers on subjects relating to inventions, improvements, discoveries, and other matters connected with the Arts, Manufactures, and Commerce of the country are read and discussed; the Meetings of the Indian and Colonial Sections, at which subjects connected with our Indian Empire and the Colonies and dependencies are considered; and the various lectures on technical subjects delivered under the Cantor and other trusts. Fellows also receive a weekly copy of the *Journal*, which contains full reports of the Society's proceedings, as well as a variety of information connected with Arts, Manufacturers, and Commerce: and they are entitled to the use of the library and reading-room.

Proposal forms and further particulars relating to the work of the Society, may be obtained from the Secretary, Mr. G. K. Menzies, at the Society's House, John Street, Adelphi, London, W.C. (2).

This number contains the Report of the Council for the year 1921-22. It is suggested that Fellows should pass on copies to any friends likely to be interested in the Society's work, and for this purpose additional copies will be supplied free on application to the Secretary, Royal Society of Arts, John Street, Adelphi, London, W.C. 2.

SOME CANTOR AND OTHER LECTURES

recently delivered before the Royal Society of Arts.

177A (Howard Lectures.) The Shortage of the Supply of Non-Phosphoric Iron Ore. Two Lectures. By Prof. WILLIAM G. FEARNSIDE, M.A., F.G.S., M.Inst.M.E. (1917) Price 1s.

78 High Temperature Processes and Products. Three Lectures. By CHARLES R. DARLINGTON, A.R.C.Sc.I., F.I.C. (1918) Price 1s. 6d.

179 The Effect of the War on the Economic Condition of the United Kingdom; the Economic Condition of the United Kingdom after 34 Years of War; Reconstruction and the real cost of the War. Three Lectures. By EDGAR CRAWFORD. (1918.) Price 1s. 6d.

181 (Cobb Lectures.) Recent Developments in Leather Chemistry. Two Lectures. By Prof. HENRY R. PROCTER, D.Sc. F.I.C. (1918) Price per set of 2 Journals, 1s.

182 Physical Chemistry and its Bearing on the Chemical and Allied Industries. Three Lectures. By Professor JAMES C. PHILLIP, O.B.E., M.A., Ph.D., D.Sc. (1918.) Price 1s. 6d.

183 The Scientific Problems of Electric Wave Telegraphy. Three Lectures. By Professor J. A. FLEMING, D.Sc., F.R.S. (1919) Price 1s. 6d.

185 Coal and its Conservation. Three Lectures. By Professor WILLIAM ARTHUR BONE, D.Sc., Ph.D., F.R.S. (1919.) Price 1s. 6d.

185A Synthetic Drugs. Three Lectures. By Professor JOHN THEODORE HEWITT, M.A., D.Sc., Ph.D., F.R.S. (1920.) Price per set of 2 Journals, 2s.

186 Recent Research in Cellulose Industry. Three Lectures. By CHARLES F. CROSS, B.Sc., F.R.S. (1920.) Price 1s. 6d.

187 The Architecture and Decoration of Robert Adam and Sir John Soane, R.A. (1758-1837) Three Lectures. By ARTHUR T. BOLTON, F.S.A., F.R.I.B.A. (1920) Price 2s. 6d.

189 Aluminium and its Alloys. Three Lectures. By W. ROSENHAIN, D.Sc., F.R.S. (1920.) Price 1s. 6d.

190 Micro-organisms and some of their Industrial Uses. Three Lectures. By A. CHASTON CHAPMAN, F.I.C., F.R.S. (1921.) Price 2s.

191 Applications of Catalysis to Industrial Chemistry. Three Lectures. By ERIC K. RIDGAL, M.B.E., M.A., D.Sc. Ph.D., F.I.C. (1921.) Price 2s.

192 X-Rays and their Industrial Applications. Three Lectures. By MAJOR G. C. W. KAYE, O.B.E., M.A., D.Sc. (1921.) Price 2s.

193 Recent Applications of the Spectroscope and the Spectrophotometer to Science and Industry. Three Lectures. By SAMUEL JUDAH LEWIS, D.Sc., F.I.C., Ph.C. (1921.) Price 2s.

194 (Howard Lectures.) Aero Engines. Three Lectures. By ALLAN E. L. CHORLTON, C.B.E., M.Inst.C.E., M.I.Mech.E. (1921.) Price 4s.

Copies of the above lectures can be obtained from the Secretary, Royal Society of Arts.
